Steel Plate Work

Before you buy anything in Steel Plate Work, send us your sketches and let us quote prices and delivery.

We specialize in turning out difficult work of this kind, built right.

Recent extensions to our shops, new equipment, a competent and experienced staff are at your service. If your job presents special difficulties, we will solve them for you.

We design and build any size, any kind of

Pressure Tanks
Storage Bins
Steel Buckets
Refuse Burners
Steel Stacks
Smoke Breechings
Riveted Steel Pipe
Cookers and Digesters
Conveyers and Elevators

We make a specialty of tanks of extra large size. Any work of this kind that you cannot buy elsewhere you can obtain at reasonable prices from our shops.

The Waterous Engine Works Co., Ltd., Brantford, Can.

Hoyt "Frost King" Babbitt Metal will prove an ideal medium between you and trouble. Forty years' experience has enabled us to give you a babbitt metal that will give extraordinary results for all classes stationary engines, pumps, rolling mills, pulp machinery and planing mills. It "stands up."

This "Nickle Genuine" is especially designed for heavy duty mining machinery, and will give the utmost satisfaction. There is one thing that is absolutely positive about this alloy and that is, it is always uniform, not only to-day, but next year and ten years from to-day.

REG. U.S. PAT. OFF.
TRADE JENKINS MARK
Jenkins Bros

"As lasting as the flanges which hold it."

Jenkins '96 should be used on your steam, hot or cold water, air and other lines, because of its complete dependability for tightness and long service.

It is a high-grade, unvulcanized sheet packing of great strength and flexibility. On steam lines it is self-vulcanizing, forming a joint that will hold under the hardest service. If the gasket is dipped in graphite or soap stone before insertion, it will not cling to the pipe and may be easily removed and used over again indefinitely.

Your regular dealer can promptly supply Jenkins '96 in the usual thicknesses, as well as standard and special cut gaskets.

Write us direct for the No. 8 Jenkins Bros. Catalogue.

PEILER'S SERVICE—

THE simple matter of buying goods at one price and selling at another never made a successful business. The ***Element of Service*** is what adds permanence to any organization, and the success of such organization is measured only by its ability to serve. The factor of ***SERVICE***—to the customer—always has been, and is, what has guided us in making connections with manufacturers of power plant specialties.

WE have had many years' experience solving difficult power plant questions, of all kinds and conditions, and the benefit of this experience is yours in dealing with us. If your conditions are not suitable for equipment supplied by us, we do not hesitate to advise what we think will overcome your difficulties.

ON this, and the opposite page, a few of our lines are shown. In our opinion, after long experience, with many tests and trials, they are the best, will stand up the longest, and give the most efficient service, of any that are made on the continent.

Mechanical Regulation of Boiler Feed Water

By the use of the "S-C" method you are assured of a continuous feed at all times load is on boiler. The graduation in rate of feeding is entirely dependent upon the load and fire conditions. The Regulator will carry a constant level on steady load—higher level on light load and lower level on peak loads. Variation in water level is entirely dependent on inclined position of generator which is adjustable while operating under full load.

Bulletin No. 80 explains all.

A Well-Insured Plant

is the power plant of the Ft. Worth Light, Heat and Power Co., Texas. On the inside the coal is stored above the boilers in a Brownhoist Concrete Bin, which time has proved will last as long as the plant and require no repairs. The coal is unloaded on the outside by a Brownhoist Locomotive Crane, which takes it from the cars and places it in storage or puts it through the roof into the Brownhoist Bin. It is safe to say that this plant will have very little trouble, if any, with its coal handling apparatus.

BROWNHOIST

Concrete Coal Bin and Coal Handling Machinery

Write for Catalog S

The Brownhoist Concrete Bin is a steel bin, lined inside and out with concrete. This protects all steel from the corrosive action of the coal or ashes. The oldest one of these bins has been in continuous service for 14 years and has required no repairs. Brownhoist Coal Handling Machines are of various types and sizes for safe, rapid and economical handling of coal. These machines and the bin are described and shown in Catalog S.

Well Equipped

The economic value of the Jones Underfeed Stoker, both in labor and coal, is rapidly being realized by a great many concerns. They readily see the scientific principle upon which the "Jones" is based. The fact that there is no smoke, no loss from sifting fine coal, no half-burned coal; all fuel must deliver **all** its heat before going to the refuse pile, has proven conclusively to a great number the enormous saving made possible by a Jones Stoker equipment.

Besides the saving in labor, the cleanliness and safety, this stoker will reduce your coal bill 15 to 25%.

If you have coal to burn you need a Jones Underfeed Mechanical Stoker. Let us get together.

War on Boiler Scale

Like a submarine, the water does not bother Perolin a bit, nor does Perolin affect the water.

It's scale that I cruise around to find. Once I find him and make my presence known he surrenders with dispatch. You see scale knows I can outmanoeuvre him every time.

Here's why:

I drop through the water until I find the weak spots in scale's line of defence. There must be these weak spots or openings, because he hasn't the reinforcements that would enable him to cover every part of the territory. Into these openings I steer my course.

So I rush in at top speed, reach Fort Hot Boiler Metal—and it's all up with scale.

He quickly ceases all resistance, releases his hold, and drops a beaten man, a mere shadow of his former self.

Then I leave an amalgam on the metal which proves a fortification that he cannot penetrate—and the battle is over, mother.

Understand through the fight I respect the neutrality of Water, Gaskets, Lubrication, etc.—only scale knows that I am harmful.

If you've hoped for warfare of this kind in your boiler. I'm at your service—and so is the booklet that gives my full story.

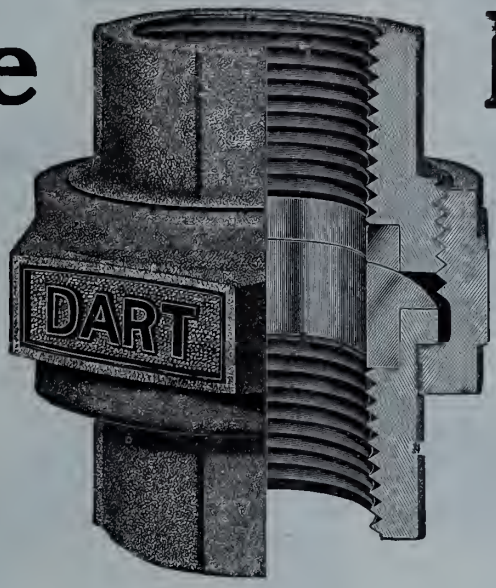
Bronze to Bronze



DART

DART

At the Joint—

And that is where the bronze is needed—at the joint, the vital part of the union, to prevent corrosion, and that is where Dart unions have it.

Then again, there is another feature, trifling it may seem, yet it adds wonderfully to its use and value. The ball-shaped seat. This ball-shape allows for an easy connection regardless of the alignment of the pipes. And of course it fits perfectly.

No leaks, no replacement, no upkeep costs. If any "Dart" union is defective in any way, we will replace it with two perfect ones.

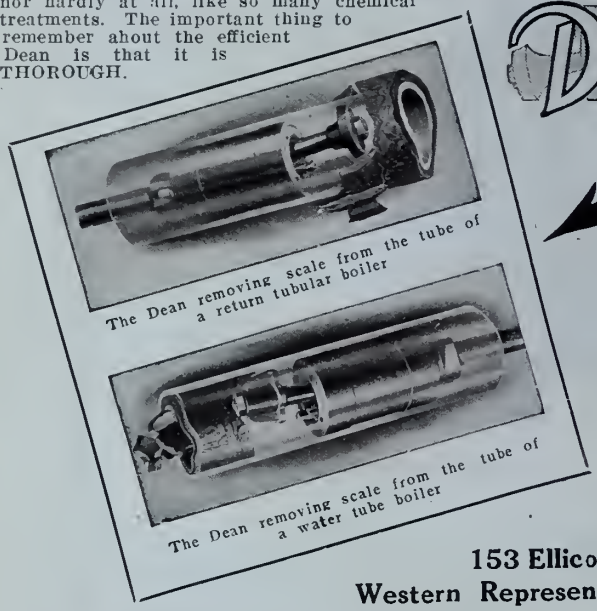
Does that spell CONFIDENCE?

Dart Union Co., Limited

Toronto Ontario Canada

Let One of These Machines Show You How It Cuts Coal Costs 5% to 35%

This machine will reduce your coal bill from 5% to as much as 35%, depending upon the amount of scale there is on your boiler tubes.
And don't say there isn't any scale on your tubes—because hundreds of engineers have received the surprise of their lives when this efficient scale remover was put through, only to bring out several hundred pounds of tube-burning, coal-wasting scale.
The Dean Boiler Tube Cleaner reduces coal bills, because it removes scale thoroughly—not partially, like so many other mechanical tools, nor hardly at all, like so many chemical treatments. The important thing to remember about the efficient Dean is that it is THOROUGH.



The Dean removing scale from the tube of a return tubular boiler

The Dean removing scale from the tube of a water tube boiler

Dean

The Dean Cleaner is operated by either compressed air or steam. Its rapid stream of vibrations on the tube wall—from 4,000 to 8,000 per minute—bodily shakes the scale loose, causes it to disintegrate, break up into small pieces and fall.
No scale, no matter how hard, thick it may be, can resist the tremendous power of vibration. The very operating principle of the Dean Cleaner is a practical insurance of complete scale removal.
If you think your present method is effective and the best possible way of removing scale, send for a Dean and try it out in competitive test. Make the Dean do every stunt you can devise—and you'll find that it will do your work quicker and much more thoroughly than you ever thought possible.

How to Order a Dean for Free Trial

We will gladly loan you a Dean Cleaner for absolutely Free Trial, without the slightest obligation on your part to purchase. To secure a Dean, simply tell us the exact outside diameter of your boiler tubes and whether your boilers are water-tube or return-tubular. If you don't want it after trial—just box it up and ship it back.

For detailed description of the Dean, ask for booklet "The Logic of the Dean."

BOILER INSPECTION

The Steam Boiler Act, Chapter 252 R.S.O., 1914, With Amendments Chapter 58—6, George V.

STEAM BOILERS.

All Steam boilers constructed for use in Ontario must be built from designs which have been approved and allotted a registration number by the Steam Boiler Branch.

Used boilers, boilers sold or exchanged, and unregistered boilers brought into the Province must be inspected prior to being put into operation.

Notice of repairs to steam boilers, stating the nature and extent of same, must be sent to the Steam Boiler Branch, and should such repairs be considered extensive by the Chief Boiler Inspector, the boilers will require to be inspected.

In each and every case the inspections must be made by Inspectors authorized to inspect boilers under the Steam Boilers Act, who are employed only by the Steam Boiler Branch of the Department of Public Works. Official certificates with the maximum working pressure stated thereon are issued to the owners of the boilers so inspected.

STEAM PIPING.

Drawings and Specifications of all high pressure steam piping must be approved and registered by the Steam Boiler Branch before any work of installation is commenced. The drawings submitted should show clearly the dimensions and layout of the main steam lines. Full particulars should be given as to the material used in the construction of the piping, and all valves and other fittings used in connection therewith must be of approved make.

Any deviation from the above requirements shall be deemed a violation of the Steam Boilers Act.

All communications in this respect should be addressed to the Steam Boiler Branch, Department of Public Works, Parliament Buildings, Toronto.

HON. F. G MACDIARMID, Minister of Public Works and Highways.
W. A. RIDDELL, M.A. Ph.D., Supt. Trades & Labour Branch

D. M. MEDCALF,
Chief Inspector of Steam Boilers.

OILS
GREASES
Etc.

TRADE MARK REGISTERED IN
NON-FLUID OIL
UNITED STATES PATENT OFFICE

Outlasts measure for measure other lubricants of any description, regardless of price.

Lubricates with least friction but does not drip, spatter and waste like fluid oils.

Lasts three to four times longer than fluid oil.

Does not require the aid of frictional heat before it begins to feed, a fault usually found in greases.

Remains the same consistency summer and winter.

Begins to feed the instant the journal starts to revolve. Feeds only when the journal turns—only as fast as needed. When you feed Non-Fluid Oil to a bearing, you have positive assurance that there will be no overheating as long as a particle of this superior lubricant remains.

We strongly advise a long accurate test of the claims we have made for these lubricants. Samples for the purpose will be gladly furnished free on request. Ask for literature giving full particulars.

NINETEEN YEARS ON CRANK PIN

VINCENNES BOARD & PAPER COMPANY.

Plain, Mill and Sheet Lined Straw and Chip Boards.

Magnolia Metal Co.. Vincenues, Ind., 7/29/16.

Gentlemen:—

I have your letter of the 20th concerning our use of MAGNOLIA METAL. I am pleased to say that we have had excellent success with this metal and have used it for a number of years in all of our hard places such as crank pins, Jordan engines and like places.

The crank pin hearing you mention was one of our Buckeye Engines. This machine was a tandem Compound and was working under an overload of about 25 per cent., and a steam pressure of 35 pounds more than the engine was designed for and yet the continous service night and day and a great many times the full week without a slow down, this would be equal to about 19 years of 10-hour days.

Yours very truly,

A. M. SHEPERD.

Jeffrey V-Bucket Elevator-Conveyer

For Small-Sized Power Plants— For Outdoor Storage of Coal

The V-Bucket Conveyer is especially adapted for handling Slack and Stoker Sized Coal. It is low in first cost; Simple, Durable and Economical in operation. May be used either as a Run-A-Round Conveyer or as a Combined Elevator and Scraper.

Built in various sizes of both Buckets and Chains to meet capacity requirements.

Write Dept. 4 about your Coal and Ashes, Crushing, Elevating or Conveying Problems.

The Jeffrey Manufacturing Company

Canadian Branch and Warerooms, Montreal

V-Buckets in vertical position mounted on "Flat and Round" Steel Link Chains, with and without guides for chains.

V-Bucket in a horizontal position with steel plate trough for buckets and steel bar strips under chains.

Upper Run of Jeffrey V-Bucket Conveyer mounted on large Roller Malleable Chain.

THE BELT WITH A GRIP

"Lincona"

BALATA BELTING

will pick up a load suddenly better than any other type of belting

BECAUSE

it has a GRIP that no other belting has and requires no dressing.

"Lincona" will give you the maximum transmission of power

"Lincona" is the strongest Balata Belt Made.

The tensile strength of "Lincona" is almost double that of leather belting and there is less stretch and straighter running than any other type of belting.

The secret of the greater strength of "Lincona" Balata Belting is in making the Balata a fluid which will saturate the duck, instead of a paste placed on and rolled in. The fluid Balata used in the "LINCONA" process also allows the duck to be compressed more closely, so producing a Belt thinner for the number of plies. This gives a stronger wearing surface to the pulley and less friction.

"Lincona" Balata Belting can be exposed to snow, rain and every condition of weather without injury. It can be run in water without trouble. Write us about your specific needs.

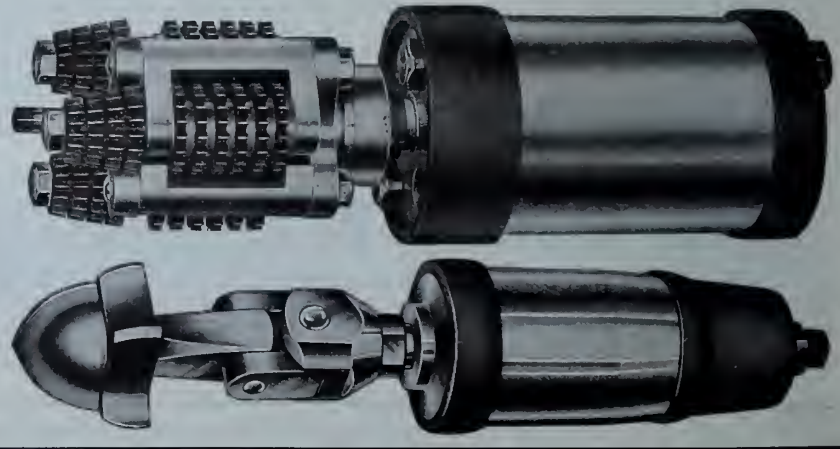
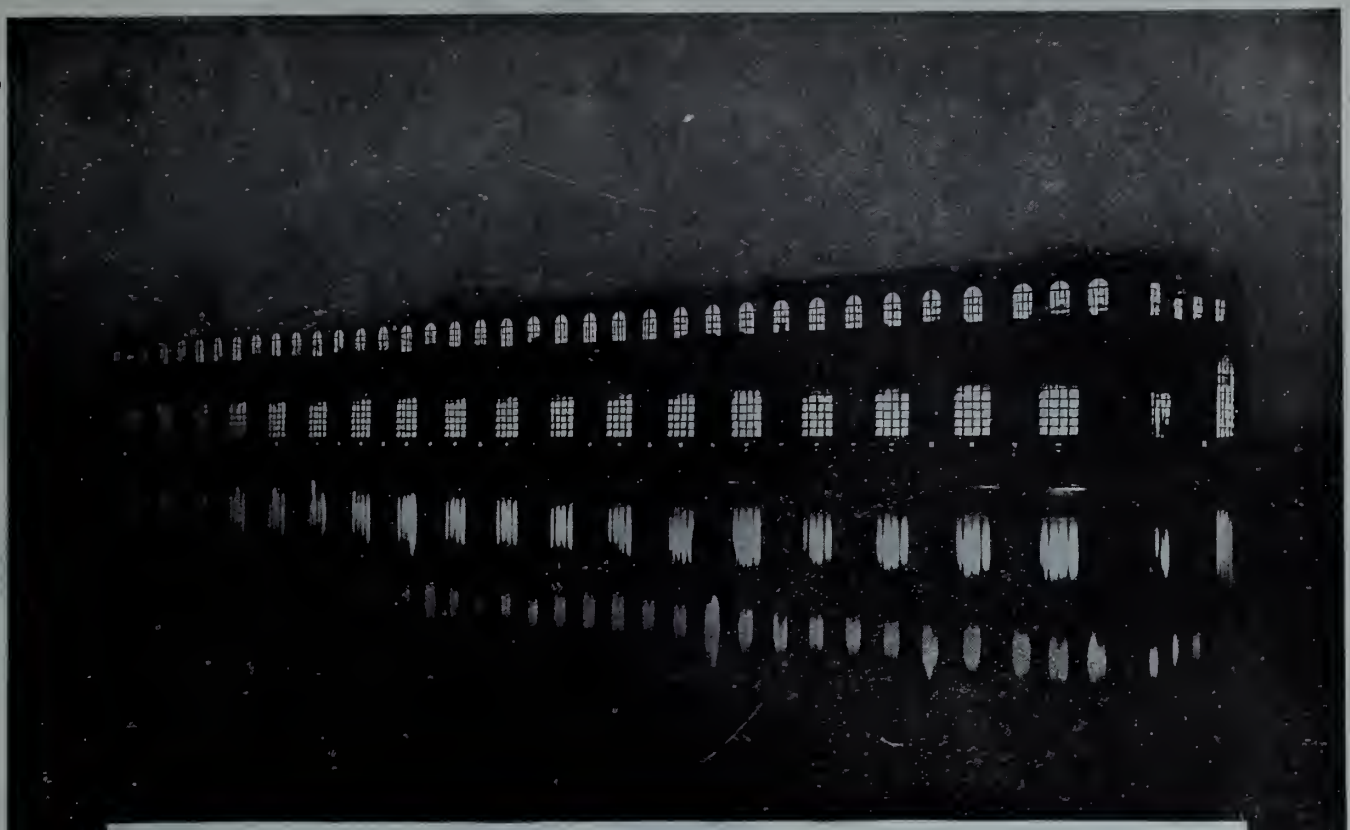
Less coal per power produced.
No burned out boiler tubes.

The only cleaners for hardest scale.
Safest and fastest for light scale.
Best for all boiler scale conditions.
Standard of the largest power plants.

THE ROTO COMPANY
Write for Catalog HARTFORD, CONN.





The Power House at Keokuk, on the Mississippi River, by night.

The World's most important power plants employ Silent Chains (MORSE, of Course)

Eleven 23 H.P. Oil Pump Drives (as illustrated below) are located in the Keokuk Power House. Seventy-two 24 H.P. drives are employed at Panama for operating the safety gate hoists. The largest chain drive in the world (5000 H.P.) drives a generator in a western power plant.

Your plant, no matter how large or small, can employ silent chain drives somewhere to good advantage—for driving pumps, governors, fans, blowers, exciters, compressors, etc., and, because of the exclusive "Rocker-Joint" construction, assuring longest chain life and greatest economy, we ask that the *make* of chain chosen be "MORSE," Of Course.

Morse Chain Co., Ithaca, N.Y.

Please send copies of your Latest Publications to the address given below. Also name preliminary proposition for a MORSE Silent Chain Drive as per the following specifications:

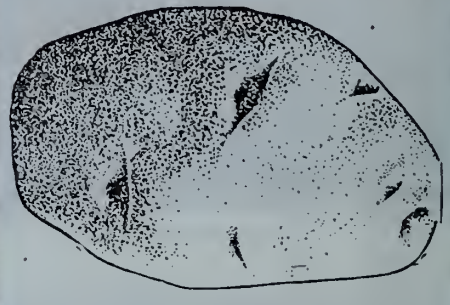
OILS

These Lubricants give remarkable service. They will keep your machinery running smoothly, easily and with a minimum of wear and cost.

No better time than now to put them to the test. The prices are very reasonable.

Potato Scale Powder Boiler Cleanser



Will positively rid your boilers of old scale and will *keep* tubes clean if but a small amount is fed daily through the feed water.

Eliminates foaming, pitting or any other boiler troubles due to impurities in the water supply. *Makes big reduction in fuel bills.*

Sold UNDER A POSITIVE GUARANTEE. Try a Barrel.

Good things for the POWER PLANT

CLING-SURFACE does the trick every time

Read these three letters, order a trial tin, give a fair test and YOU will be just as enthusiastic.

"How am I coming on with Cling-Surface? I am not coming on—I AM on. No slip. No squeak. Running like a top. What more should I want?"

And in the same mail, another: *"Good belt service from Cling-Surface is the best paying investment in our place."*

And still another: *"Cling-Surface caused a 5-in. and a 6-in. belt to take to the center of the pulleys, when before they drove to one side."* (*Names on application*).

A trial of Cling-Surface at a few cents cost will bring you *immediate, marked* and *lasting* belt improvements. Send at least for literature.

We quote f.o.b. Toronto.

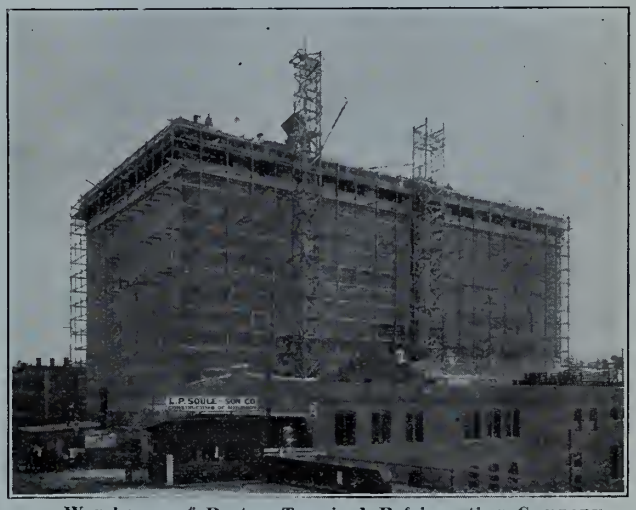
Under Water Twice-a-Day for Six Years

The Boston Terminal Refrigerating Company, East Boston, Mass., have three 6-inch suction lines laid in an ordinary non-waterproof concrete trench. The bottom of this trench is two feet below high tide level. Consequently, the

NONPAREIL CORK COVERING FOR COLD PIPES

with which the lines are covered, is under water twice-a-day. This is exceptionally severe service, such as is seldom encountered. Even so, the Nonpareil Covering is giving perfect satisfaction; and, in the words of the Judd Engineering Company, Boston, Mass., who made the installation,

"We were obliged to bale the water out of this trench, dry it, and insulate the pipe between tides. The plant has now been in operation for a period of six years, and we have never had the slightest trouble with these pipes."



Warehouse of Boston Terminal Refrigerating Company, East Boston, Mass.

Incidentally, the warehouse, which is shown above, is insulated throughout with Nonpareil Corkboard. It contains 1,500,000 cubic feet of cold storage space, yet last summer only 6,000 pounds of coal per 24 hours were required to run the entire refrigerating plant, three hydraulic elevators, and the generator for light and power.

The remarkable service that Nonpareil Cork Covering and Nonpareil Corkboard give is due to the high insulating quality of the cork and its remarkable ability to resist moisture.

High Duties From De Laval

Steam Turbine Driven Centrifugal Pumps

De Laval Steam Turbine-driven Centrifngal Pnmps have long held the records for efficiency. The latest is 168.3 million foot lb. per 1,000-lb. steam at 140-lb. gage and 100° F. superheat, established by a De Laval Turbine-driven Pump at the Low Level Pumping Station of the Montreal Water Works. This pump supplies 30,000,000 Imperial gallons per day against 210-ft. head.

The high dnty turbine-driven centrifngal pnmp was made possible by the De Laval Donble-helical Speed-redncing Gear. Speed-redncing Gears can be nsed to advantage with centrifngal pumps wherever high tnrbine and high pnmp efficiency are desired, or where relatively large volumes of water are to be pnmped against low heads as **in circulating condenser water.**

Where small quantities of water are to be pumped against high heads and where the exhanst of the tnrbine can be nsed in feed water heaters or manufactnring processes, directly connected nnits are more simple and less expensive. **Turbine-driven centrifugal boiler feeders,** for example, are bnilt in sizes from 2,000 to 50,000 boiler horsepower. There are no parts in actnal contact, except the bearings and the simple packings about the shaft and no valves, plungers or pistons. All working parts are accessible upon lifting the casing covers and withont disconnecting piping. The feed line is free from shock, which is favorable to the use of boiler feed regnlators. The exhaust steam is uncontaminated with oil.

De Laval designs are distingnished by moderate peripheral speeds, large running clearances, horizontally split casings and accessibility, close regnlation, limit gage method of mannfacture, and interchangeability of parts, and every unit is guaranteed and tested before shipment.

The many different applications of centrifugal pumps, together with their Design, Manufactnre, Testing, Characteristics and Selection are fully explained in our 300-page Book B61.

Plant and Equipment of Vancouver Ice and Cold Storage Co.

By A. F. Adams *

Ice manufacture and cold storage have in recent years become what might be termed staple industries, and, in the case of the Pacific Coast, the growth of such plants has been parallel with the development of the principal products of the country. Fruit and fish are two items alone, the commercial success of which has been greatly facilitated by the availability of such substantially equipped plants as are described and illustrated in the following article.

THE plant of the Vancouver Ice & Cold Storage Co., Ltd., at Vancouver, B.C., is located in close proximity to the water front and consists of three buildings arranged as shown in Fig. 1, the main engine room being located in No. 1 building, while Nos. 2 and 3 buildings contain ice tanks and ice storage rooms. A 40-ton compressor, however, is located in No. 3 building, to be used in case of emergency, or in the event of fire or accident putting the main plant out of commission. The wisdom of this arrangement was demonstrated in May, 1916, when a destructive fire occurred on the wharf, completely destroying a large hay and grain establishment along with a grain elevator. The damage sustained by Nos. 1 and 2 buildings was confined to the roof as a result of the efforts of the fire department, assisted by a favorable wind. These buildings are of wooden construction throughout, while No. 3 building is of tile and concrete, and as far as possible, is fireproof. An exterior view of No. 3 building is shown in Fig. 2, with the railroad tracks at the head of the buildings; an interior view is also given in Fig. 9.

Compressor Installation

Four ammonia compressors, ranging from forty to one hundred and thirty-five tons capacity, are installed in No. 1 building. They are all of the horizontal double acting type, and include both steam and motor-driven units, their capacities, etc., being as follows:—

One 40-ton Triumph compressor, built by the Triumph Ice Machine Co., Cincinnati, chain-driven by a 75-horse-power, three phase, 2,200 volt Westinghouse three bearing motor.

One 65-ton Linde compressor built by the F. W. Wolf Co., Chicago, driven by a 16 in. x 42 in. simple Corliss engine made by the Minneapolis Steel & Machinery Co.

Two Niebling compressors, one 75 and one 135 tons capacity, built by the F. W. Niebling Co., Cincinnati. The smaller machine is driven by a 12 in. x 24 in. x 30 in. tandem compound Corliss engine, made by the Laurie Engine Works, Montreal. This unit is shown in illustration, Fig. 3, while the larger machine is shown in Fig. 4. This latter machine is rope driven by a 400 horse-power, three phase motor, see Fig. 5, the reason for such a large motor being to provide for the installation of another compressor as soon as the demands of the business justify it.

The growth of the business is illustrated by the fact that a 30 kw. set formerly used for lighting and elevator service, is not now sufficient for all of the buildings and is only used as a standby for lighting purposes. This unit is shown in Fig. 6, the generator supplying 220 volt a.c. current. It is direct connected to a Robb engine, with exciter on same shaft. The switchboard, one end of which is visible in Fig. 6, is fully equipped with transformers, volt meters and ammeters. The Robb engine has a stroke of 9 in. with a cylinder diameter of 8 in., and operates at 400 revs. per min.

Boiler and Condenser Plant

Steam requirements of the entire plant are supplied by two Babcock & Wilcox water tube boilers of 300 horse-power capacity. See Fig. 7. This includes steam for the engines and pumps, and also the steam requirements of a large ice cream plant, which occupies a portion of No. 1 building. The boilers are fired by mechanical stokers of the Babcock & Wilcox chain grate type, being driven by a small steam engine, which also drives the fan for the induced draft system. The control of this engine is of an interesting nature, the speed being governed by a regulating valve in the steam line, which passes more steam to the engine if the pressure falls, giving increased speed and feed to the stoker, while the reverse operation takes place if the steam pressure rises. Very little variation of the steam pressure takes place with this system of firing control. A motor operated bucket conveyor takes the ashes to an overhead hopper.

The steam pressure carried is 160 lbs. per sq. in., which is reduced to 115 lbs. for the simple Corliss engine and pumps, by means of a Davis pressure regulator. Boiler feed requirements are taken care of by a standard Weir feed pump, a Penberthy injector being installed for emergency use. A Webster vacuum feed water heater and purifier is installed which raises the temperature of the feed water to about 210 deg. F.

The exhaust steam from the compressor engines passes into a surface condenser, the vacuum pump being of the Fairbanks-Morse direct-acting type, a vacuum of 26 in. of mercury being maintained regularly. A Cranetilt vacuum trap is installed on the exhaust line between the engines and condenser for the purpose of removing oil and condensation from the line which it does without destroying the vacuum.

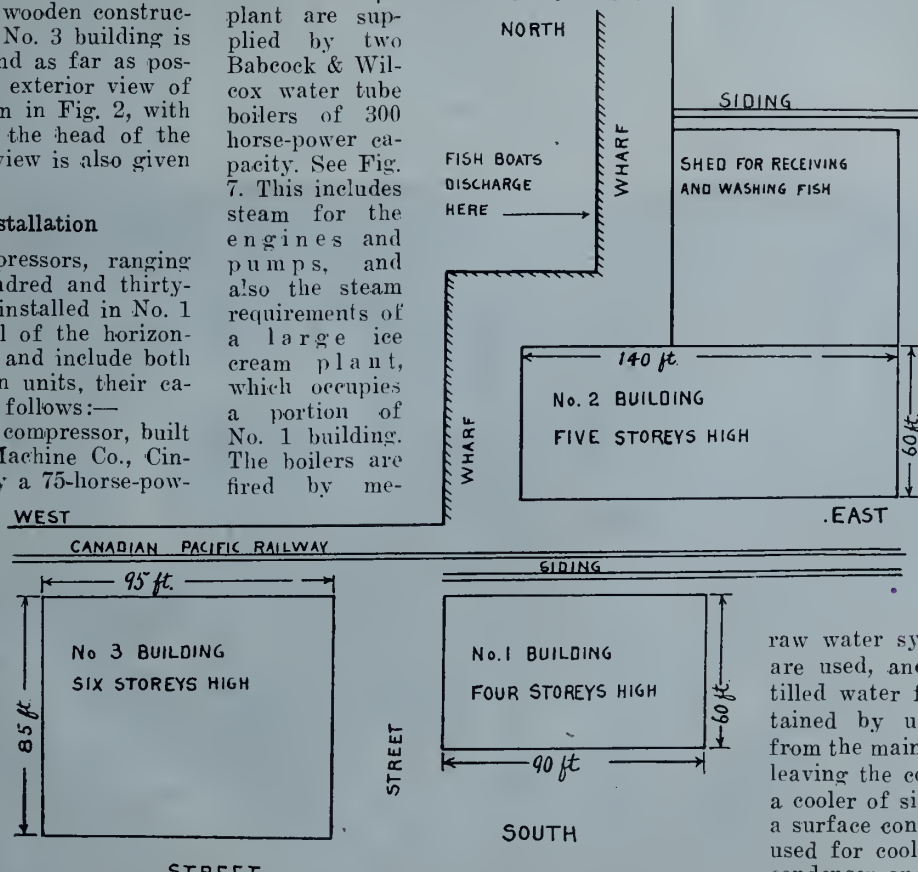

FIG. 1. PLAN OF VANCOUVER ICE AND COLD STORAGE CO. PLANT, SHOWING LOCATION OF BUILDINGS AND WHARF.

Cooling Water Systems

Both distilled and raw water systems of ice making are used, and the supply of distilled water for the former is obtained by using the condensate from the main engines, which, after leaving the condenser, is cooled in a cooler of similar arrangement to a surface condenser. Sea water is used for cooling purposes in both condenser and cooler, being circulated by a Weir land type of feed pump, the use of salt water necessitating a bronze water end on the pump. Temperatures of this cooling water during 1916 were 54 deg. F., in July, and 46 deg. F., in November. The sea water is obtained through an 8-in. cast iron pipe laid in a tunnel, which passes underneath the railway tracks, the maxi-

*Plant Chief Engineer.

mum lift of the circulating pump being fourteen feet at low tide, decreasing to a minimum at high tide. A duplicate pump installation is installed in connection with this system.

The ammonia condensers in use are of both atmospheric and counter-current double pipe types, and are cooled with fresh water which is maintained at a suitable temperature by a cooling tower carried well up above the roof of the building to secure a good circulation, Weir pumps being used in connection with the cooling tower.

Ice Tanks

The ice tanks and ice storage rooms are located in Nos. 2 and 3 buildings. As mentioned above, both distilled and raw water systems are in use, but the conversion of the plant to the manufacture of raw water ice entirely is at present under consideration.

The McCormick raw water system is employed, in which the drop pipes are connected to a header, which is removed from the tank when the ice is formed, other systems requiring the removal of one or two pipes, per can as the case may be. A very satisfactory blower is used for supplying air to this ice system, being the product of a local firm and having been in constant operation for the past eighteen months. This machine is particularly quiet in operation and gives as good service to-day as when first installed.

The distilled water ice tank is fitted with special handling apparatus which enables the crane to lift twelve cans at once instead of one or two, as ordinarily done. After being lifted from the tank, the cans are dipped in warm water which loosens the ice, after which the cans are lowered into such a position that the loosened blocks of ice slide out on to an elevator platform. The elevator lowers the ice to the storage room, which is immediately below the freezing tank, thus making it unnecessary to lift the ice at any stage of manufacture. Standard 300-lb. cans are used, and storage is provided for 1,500 tons of ice.

FIG. 2. EXTERIOR VIEW OF NO. 3 BUILDING.

Fish Freezing and Storage

In addition to ice making, No. 2 building is used for freezing and storing fish for local firms. The interior of one of the freezing chambers is shown in Fig. 8, the temperature when the photograph was taken being 12 deg. F. below zero. The method of refrigeration followed in this plant is to have a temperature of at least 5 deg. F. below zero, using lower temperature if the fish are large, and freezing as much as 100,000 pounds in one batch. When thoroughly frozen, the fish are taken to the dipping and packing room adjoining the freezers, and in which the fish are maintained at a constant low temperature until they are glazed and packed, after which they are placed in the storage rooms, where they

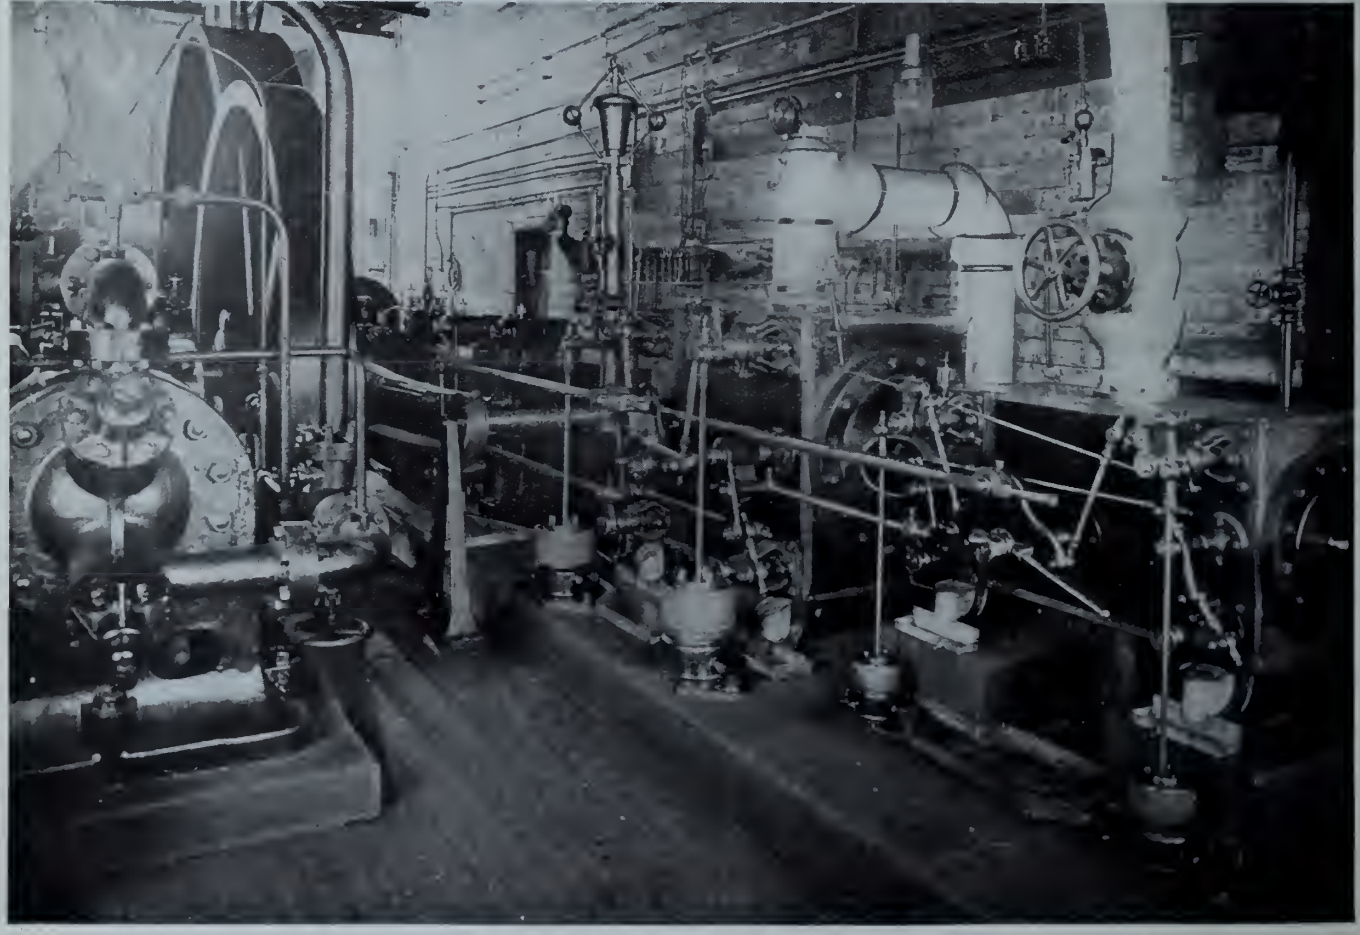

FIG. 3. 12 IN. X 24 IN. X 30 IN. TANDEM COMPOUND CORLISS ENGINE DRIVING 75-TON NIEBLING COMPRESSOR.

remain until shipped out to dealers.

The requirements of the local fish trade in crushed ice are also supplied by this company, an ice crusher being conveniently located for this purpose. It is about 25 ft. high and is operated by a 15 horse-power Westinghouse motor. An endless chain elevator raises the ice to the crusher, from which the crushed product is delivered by a chute which can be raised or lowered to suit conditions of removal.

All storage rooms requiring low temperatures are equipped with direct expansion cooling, while the fruit, cheese and egg rooms are cooled by means of cold air. All of the egg storage rooms are equipped with the Madison Cooper system of egg storage. Various items of special equipment are provided, amongst them being a Vajens improved head pro-

FIG. 8. INTERIOR OF FISH FREEZING CHAMBER AT 12 DEG. BELOW ZERO.

tector, a Westinghouse air compressor for testing piping, an ammonia distiller and purifier, and a Crosby indicator outfit.

Operative Improvements

One or two improvements effected by the writer during the past three years may indicate the possibilities available in other plants. In former days an additional freezing tank had been added to the original installation in No. 2 building, but the desirability of increasing the return suction line to the compressor had to be overlooked. It was therefore decided to increase this to take proper care of the enlarged freezing capacity. The original line consisted of 2½ in. pipe laid in a box filled with sawdust and covered to a depth of three feet. The new line was increased to 5 in. dia., and covered with nonpareil cork covering, and, in place of being laid in a box like the old pipe, was placed in a wooden pipe, such as is used for water mains. The bore of the wooden pipe was considerably larger than the outside

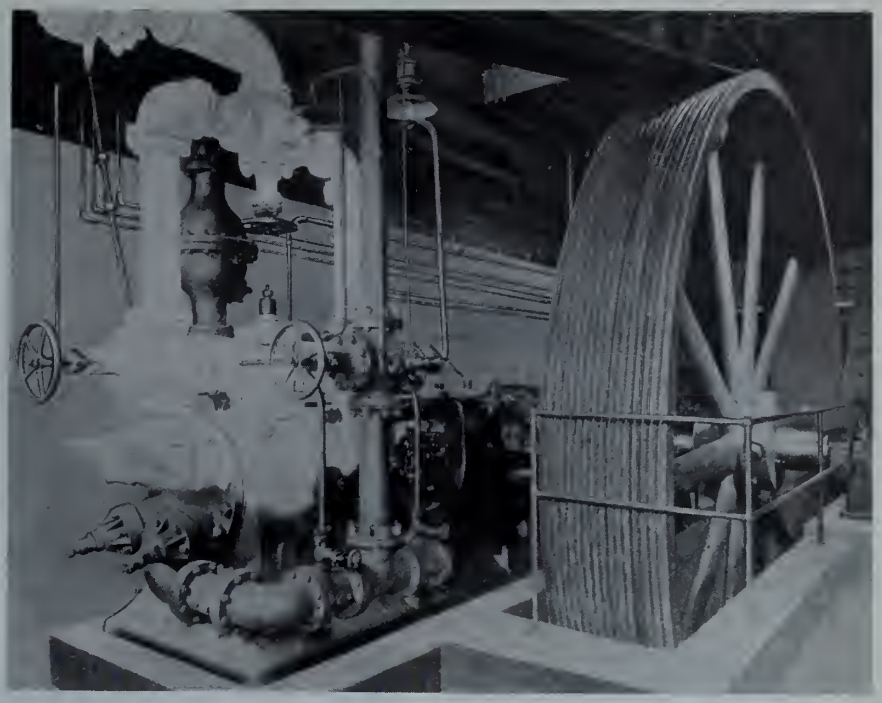

FIG. 4. 135-TON ROPE-DRIVEN NIEBLING COMPRESSOR.

diameter of the cork covering on the suction pipe, and the length was seventy-five feet. The pipe was laid to the required depth and extended under the railway tracks, being laid at a suitable inclination to insure drainage.

The lengths of suction pipe were now covered and pieces of 2 in. x 4 in. scantling were beveled on one edge and fitted to the under side of each length when it was ready to enter the wooden pipe. These scantlings acted as skids and prevented injury to the cork covering as each length was added to the suction pipe and the whole drawn further through by block and tackle. The skids kept the suction pipe in the centre of the space, leaving room all around to see through from end to end; as a good draft was always present a leak would very quickly be detected. The effect of this alteration was immediate and marked, the gauge at the compressor showing an increase of from 3 to 5 lbs. per sq. in.

General Efficiency Improvements

Attention was next given to the pipe lines throughout the plant, a considerable sum being invested in cork coverings, while traps were installed at all points where pockets were formed, allowing oil, etc., to accumulate till large quantities came over to the compressors, so that broken valves, springs and spindles were of frequent occurrence. Reduced condensation and effective

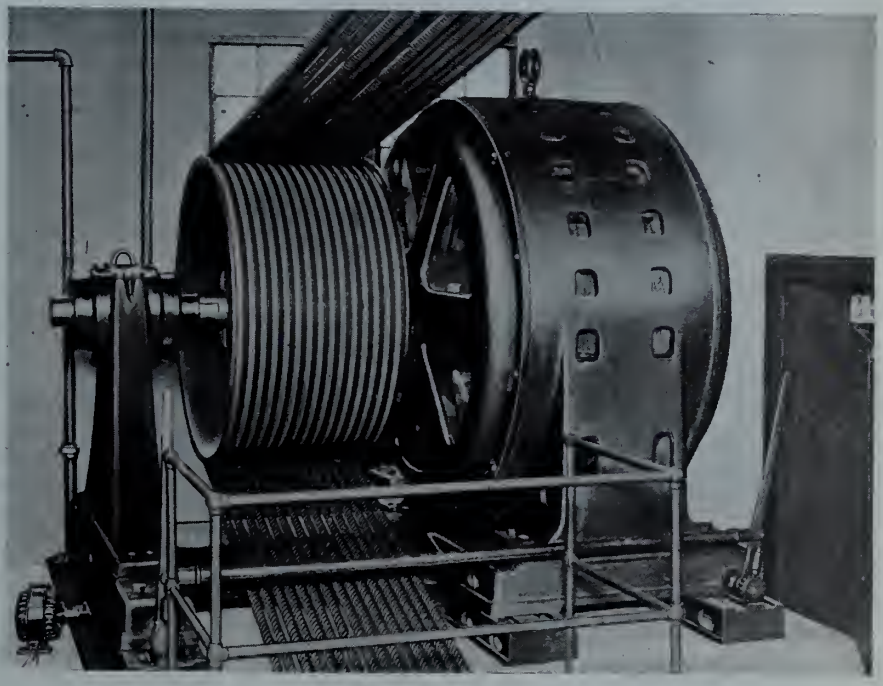

FIG. 5. 400 HORSE-POWER THREE-PHASE MOTOR WITH ROPE DRIVE.

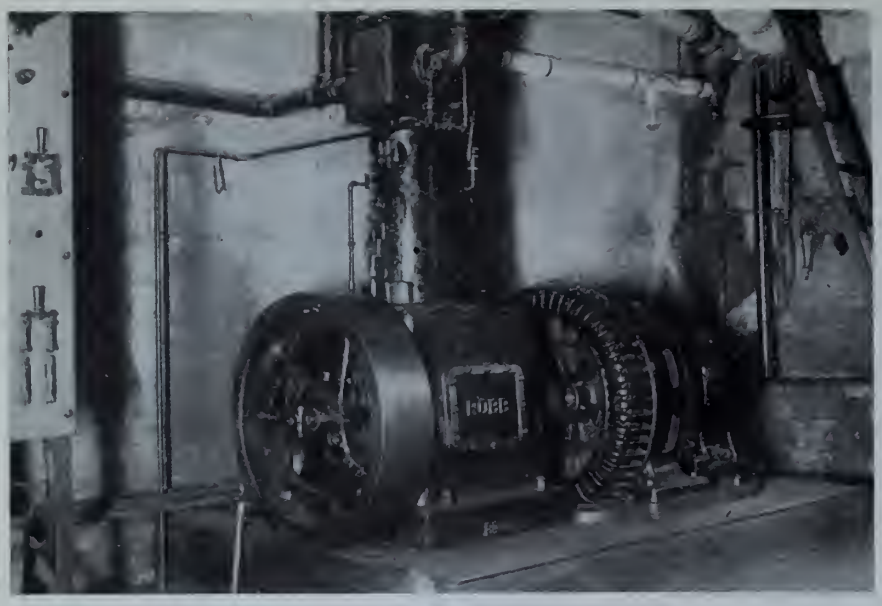

FIG. 6. ROBB HIGH-SPEED ENGINE-DRIVEN SET OF 30 K.W. CAPACITY.

drainage, brought about by the improvements referred to, resulted in only one valve spindle being broken in three years; the traps assisted greatly in the work of the ammonia purifier, the time for draining them being indicated by thawing-off taking place.

The continued growth of the fishing industry imparts a considerable degree of importance to the cold storage business, without which many allied fields of activity would be greatly restricted. The principal officials of the Vancouver Ice & Cold Storage Co. are Captain J. J. Logan, president; L. E. Harbur, manager; with A. Boggie in charge of fish freezing and storage.

FIG. 9. INTERIOR OF ROOM IN NO. 3 BUILDING SHOWING PIPING AND CONCRETE PILLARS.

FIG. 7. BABCOCK & WILCOX WATER TUBE BOILER OF 300 HORSE-POWER CAPACITY FITTED WITH CHAIN GRATE STOKERS.

ONTARIO BOILER RULES REVISION

A PROPOSAL is under consideration to revise the Rules and Regulations covering the construction and inspection of steam boilers in the Province of Ontario. A meeting was called by Dr. Riddell, superintendent of the Trades and Labor Branch of the Department of Public Works at the Parliament Buildings, Toronto, on Dec. 28, for the purpose of ascertaining the views of those interested. It is proposed to prepare a bill for presentation before the Provincial House, which will be a revision of the Act already in force. The delegation consisted of representatives of steel and cast iron boiler manufacturers, boiler inspectors, stationary engineers.

Dr. Riddell in calling the meeting to order asked for a frank discussion of the proposed rules and said he would be glad to receive any suggestions that might be helpful in the preparation of a Bill that would meet with the approval of all the interests concerned. The proposed rules which were read by D. M. Medcalf, chief boiler inspector were discussed in detail and suggestions taken down in the minutes.

At the conclusion of the meeting it was decided to send copies of the minutes to all boiler manufacturers, inspection companies, etc., who will in turn submit their views to Dr. Riddell. It was further decided to appoint a committee composed of two representatives from each of the following interests:—Steel boiler manufacturers, cast iron boiler manufacturers, boiler inspection companies, stationary engineers, boiler users, and manufacturers of fittings. The committee will confer with Dr. Riddell and will be authorized to make any suggestions which will tend to improve the present Act.

CANADIAN POWER PRODUCTION

THE generation of electricity in Canada, and its division as between domestic and export business, is dealt with in the report of the Inland Revenue Department, issued December 22. It is of especial interest because of the discussion as to exportation of electrical energy.

The Canadian Niagara Co., figuring on the basis of kilowatt hours, produced 400,521,090 units for export, and 11,178,910 for use in Canada. The Electric Development Co. exported 34,652,000, and produced for use in Canada 395,346,500 units. Other companies divided their production as follows:

	Export	Domestic
Ontario Power Co.	199,135,160	616,834,440
Ontario and Minn.	13,144,070	11,789,534
Cedar Rapids Co.	358,753,000	56,031,000
Sherbrooke Power Co.	230,820	8,605,200
Maine & N.B. Co.	3,075,893	242,437
Western Canada Co.	11,937,700	60,468,020
B. C. Electric	330,626,680	470,689

On an examination paper the following question was asked: What is steam?''

One engineer said: ''Steam is water in terrible sweat.''

Power Transmission Section

FRICTION CLUTCHES—II.*

By W. G. Gass.

IN our December issue a resume was given of the different types of friction clutches manufactured, examples of which are to be found installed in lesser or greater number as part of the transmission equipment of general industrial and metal-working plants. The driving surface feature was discussed at some length in the same issue.

Clearances

Clearance is the main difficulty in the general run of clutches, and the smallness of it is the cause of a considerable amount of wear when running out of gear. In all cases where the setting-up is done by screws, the clearance between the driving part and the driven is a relatively small amount. The cone gives the largest amount of any, and on that score alone is the best. In segment clutches, both inside and outside band clutches and plate clutches, it is a very serious problem. In the majority of these, where a screw is used, the usual amount of rotation of the screws is about ⅛th of a revolution, and if screws of say ¼ in. pitch are used, right and left hand, the movement given to the segment is 1-16th of an inch—1-32nd on each side, and that represents the clearance when the clutch is out of gear; the actual clearance is less than this owing to the shape of the segments.

Setting Up Gear

In all cases the action of setting up a clutch is the conversion of a sliding movement along the shaft carrying the clutch into a pressure between the clutch surfaces. This may be properly divided into two portions, the first that which is in the clutch itself, and the other by which the power for operation is applied. In the majority of clutches the locking and concentration of power obtained by the toggle motion is the one mostly adopted, and when once set up has no tendency to slip back. It requires in every case an adjustment by means of a screw which can be set so as to bring the levers in the correct position to give the requisite pressure on the surface.

*Read before the Manchester Association of Engineers.

In most of the internal and external segment and band clutches the adjustment is obtained by moving the main nuts a portion of a revolution and relocking—the nut having a serrated rim with a locking pin. In plate clutches it is generally done by using the adjustment screw at the point where the pressure to the plates is applied. In others, the forcing of the surfaces in contact is done by a wedge, having at its larger width a parallel portion which takes the end thrust off when the clutch is set up. The wedge is flat in some and circular in others.

With both the toggle point and the wedge, a sliding block is necessary to transmit the power from the stationary lever to the rotating shaft carrying the cluch. In the majority of cases the power is applied to the clutch to set it in gear, but, in others, the power is applied to release it or put it out of gear, the clutch being kept in gear by means of springs. Motor car clutches are the most common examples of this kind. For general machine driving, where a rapid movement is required for operating the clutch, a lever is usually employed, and if the leverage be sufficient, is quite satisfactory. It enables the power to be applied quickly and as quickly released, and where it is desired to give a slight movement to the machine, and also where the clutch is put in gear and released many times. Where a clutch is in gear for long periods, a screw and quadrant is mostly used. This is as generally fitted to internal combustion engine drives. It gives an easier starting movement because the pressure can be more gradually applied, but it is much slower both at starting and releasing. Where the lever is used, particularly on a heavy clutch, it requires a strong pull on the part of the attendant to put the clutch in gear. The trouble with all setting-up gears is the wear on the pins and lost motion due to clearance in bearings.

Pressure on Working Faces

This is the crucial point in the efficiency of any clutch and its power to drive, for unless the necessary pressure exists between the frictional faces the clutch cannot transmit its power, and it is here where so much trouble arises in the use of any form of friction clutch. The power of any clutch is of course dependent on the co-efficient of friction between the surfaces, and whether they are dry or lubricated, and it is this factor which so materially affects any formulae for the power of a clutch. The co-efficient of friction varies greatly with the state of the surfaces, and, after the surfaces become glazed the power of the clutch drops in unison.

It is usually considered that if an actual pressure of 50 lbs. per square inch can be put on the surfaces it is as much as is desirable for good working conditions; but, if for any reason a less pressure is put on than that required to transmit the power, a clutch will, if it begins to slip, grind itself away quickly, and in the spring centre type grind away all the available spring in the metal. On looking at the action of the toggle joint it will be seen that the travel of the portions of the clutch being set up is very slight at the end of the movement, when the thrust link of the toggle is approaching the vertical. Pins are essential, and, in spite of all that can be done, will wear, so that if a clutch is set up correctly a very small wear on the pins and links of the toggle will rapidly reduce the effective pressure of the faces, even without taking into account the wear on the frictional surfaces.

It is, therefore, very necessary to keep a watch on a clutch to see that any wear which may take place is followed up, if the life of a clutch is to be as long as it ought to be. Where the pressure on the surface is due to springs, and these usually are in direct thrust, then they will follow up a considerable amount of wear themselves. It appears from this as though springs were the best, but they are only good where conditions are suitable, and this is not generally so for driving machines. The remarks about wear apply equally to wedge setting up surface. The power transmitted is proportional to the speed of rotation, and a clutch which will transmit 10 horse power at 100 revs. will of course transmit 50 horse power at 500 revs.

Lubrication

In clutches, as in everything else, lubrication is of the greatest importance,

and more particularly where the clutch is running idle for a considerable part of its time. If the outside portion of the clutch is the driven part, it runs on the shaft and may have to be stationary while the shaft rotates in the clutch bushes; or, if the outside is the driver it has to run loosely on a stationary shaft. This is a fruitful source of trouble with many clutches, and the lubrication of these bushes requires the closest attention, both in design and on the part of the attendant. If the driven portion has to be stationary while the shaft runs in it, there is a tendency for the shaft to wear a groove in the bush, and, when this starts, it rapidly grows worse as this part always seems to stop at the same point and be worn oval; while if the driving portion has to run loose on a stationary shaft, the bush wears larger and affects the clearances, even sometimes becoming so bad that the friction surfaces never run clear and are always rubbing. When in gear the lubrication is not required, and the oil is liable to be driven out of the bearing surfaces and so be missing when wanted.

In starting up any friction clutch a certain amount of rubbing takes place, and when two metal surfaces rub on one another fine particles of metal are given off. These, in an enclosed chamber, cannot get away and so become mixed with the lubricant, and form an excellent abrasive which does not increase the life of the parts. Another peculiarity of lubrication in the case of plate clutches is that where the resistance to the idle clutch is not very great, if the oil becomes thick the plates adhere because all the air is driven out between them, and the resistance may not be able to make the clutch stop. Springs between the plates have been tried to get over this, but the results have not been very satisfactory. Excessive lubrication also reduces the driving power materially. Solid grease has much to be said on its behalf for lubrication of clutch hubs, but it is often difficult to employ it satisfactorily.

CANADA'S 1916 COAL OUTPUT

THE Dominion Department of Mines has received from the principal coal operators in Canada returns of their production for ten months, supplemented in most cases with estimates for November and December.

On the basis of the record available, it is estimated that the total production of coal in Canada during the calendar year 1916 will approximate 14,365,000 short tons (equivalent to 12,825,892 gross tons). The estimate is believed to be fairly close for Nova Scotia and British Columbia. In Alberta, however, there are so many small operators that final returns may show a wider variation from the estimates now made. By provinces the estimate is as follows, the figures for 1915 being included for comparison:

	1915.	1916.	Inc.
N.S.	7,463,370	6,950,000	*513,370
N.B.	127,391	135,000	7,609
Sask.	240,107	260,000	19,893
Alberta	3,360,818	4,400,000	1,039,182
B. Columbia..	2,065,613	2,620,000	554,387
Yukon	9,724	.....	.....
Total	13,267,023	14,365,000	1,097,977

*Decrease.

The 1916 production exceeds that of the two previous years, the increase over 1915 being about 8 per cent. Nova Scotia is apparently the only province that has not made an increased production, the falling off in this province being a little less than 8 per cent. The increase in Alberta is nearly 32 per cent., and in British Columbia nearly 27 per cent. The production in New Brunswick, Saskatchewan and British Columbia is the highest on record. No estimates are available yet as to the Yukon output.

AIR CYLINDER EXPLOSION

AN alarming explosion of a compressed air cylinder worked in connection with a large gas engine has come to our notice, says *Vulcan*, and as so many of these high-pressure cylinders are now in use for starting purposes, the facts of the case are of interest.

It is sometimes asserted that air receivers are not liable to corrode or develop other defects on the inside, and, apparently, in accordance with this view many receivers are made without provision for internal examination. Experience with these vessels, however, shows that there is sufficient moisture in the air to cause serious corrosion, and that this is often aggravated by grease deposited from the compressor. For this reason facilities should always be afforded in air cylinders for proper periodical cleaning and examination on the inside. The ends of such cylinders also should

LAMINATIONS IN EDGE OF FRACTURED COVER.

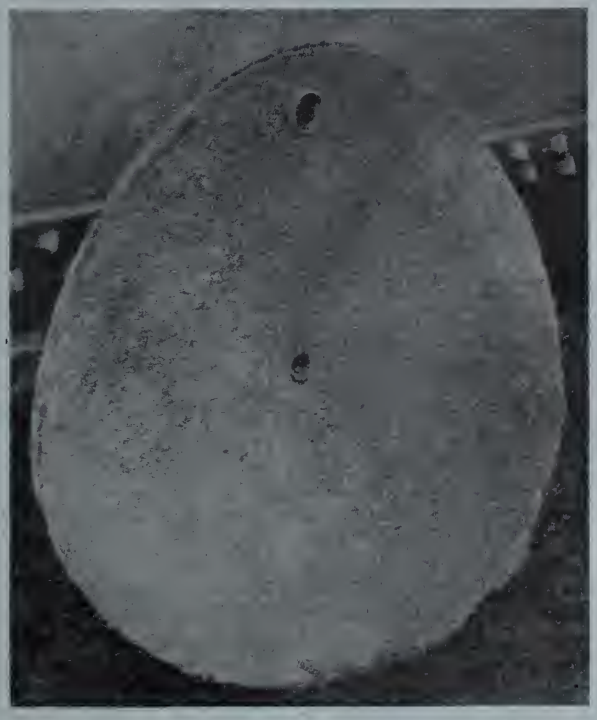
be of ample strength and well dished, unless otherwise strengthened by stays.

The cylinder in question was worked at a pressure of about 200 lbs. per square inch, and was made of iron plates about 3/8 in. in thickness originally. The ends were nearly flat and the material, judging from the quality of the end which failed, was of very inferior quality. This

END OF AIR CYLINDER SHOWING FRACTURE.

plate was badly laminated for nearly its whole circumference and also corroded, and owing to the panting action which inevitably occurred with a circular flat plate under the working conditions, grooving was set up at the root of the flange attaching the end to the cylindrical body and eventually weakened the end to such an extent that it was blown out. The explosion was a violent one, the top end of the cylinder being thrown through the roof and into a field about 100 yards away. The windows of the engine house were damaged and the engine attendant had a narrow escape.

Air cylinders of this type intended to work at high pressures should be very carefully designed. The material should be of the best mild steel of ample strength, and for a diameter of 2 ft. the size of the cylinder in question, the ends should have been about ½ in. thick and dished to a radius not less than the diameter of the receiver, which in the present instance would have been about 4 in. to 5 in., whereas the actual camber of the ends was only about ¾ in. Where flat or nearly flat ends are used the plates should be adequately stayed with bolts or other means. Should an air receiver be too small to fit an ordinary pressed steel manhole and cover, hand or side openings should be provided near each end, so that the flange portion of the crown plates can be examined periodically for grooving or other defects. Air cylinders should also have a drain at the lowest point for washing-out purposes, and, of course, a suitable safety valve and pressure gauge.



AIR CYLINDER COVER FOLLOWING EXPLOSION.

BOILER INSPECTION REPORT, DEPT. PUBLIC WORKS PROVINCE OF ONTARIO

THE enormous increase in the cost of steel since the outbreak of the war has affected to a quite considerable extent the manufacture of boilers in Ontario as elsewhere by reason of the necessary increase in the selling price. This increased cost of new boilers has created a great demand for secondhand boilers—not altogether on account of cheapness for high prices are being paid—but by reason of their being more or less immediately available. Many old and discarded boilers which in normal times would be sold as scrap or left rusting in vacant places around our factories have been cleaned and painted and put on the market for sale by boiler dealers, a circumstance calling for extra vigilance as far as inspection goes.

A slight alteration has been made in the Steam Boiler Act, section 2, subsection D. which formerly read:—

"A portable boiler rated at 25 horse power or under, or a boiler used exclusively for horticultural or agricultural purposes." The words "rated at 25 horse power or under" have been omitted. This change in the Act gives jurisdiction over portable boilers used in public places in conjuction with contractors equipment, etc. Boilers of this kind formerly were not built from registered designs and were exempt from provincial laws. The fact that those boilers are often used in close proximity to hundreds of people is good reason why their designs should be of the most approved type, and also why they ought to be inspected annually.

It will be noted from the list of inspections that in addition to boilers, a number of air tanks have been examined during the past year. This inspection work was made at the request of the owners of these vessels and the customary fee of $5.00 per tank was paid by them. The safe working pressures were determined from the rules governing the construction of steam boilers, and the same certificates as issued for used boilers were made out for these vessels.

During the past year ten boilers have been inspected for British Columbia. Arrangements were made during 1915, whereby the inspection of all stationary boilers built in Ontario for British Columbia would be carried out by Inspectors of this branch. Some trouble was previously experienced by manufacturers on account of their boilers being re-examined on arrival at their destination, and sometimes the safe working pressure was reduced on account of defects in the workmanship. The boilers examined during the past year have been accepted by the British Columbia authorities without being penalized in any way. During normal times the number of boilers built in Ontario for British Columbia would of course be much more than last year's total.

For some time past, and more especially since the fatal steam valve explosion at the Greey Foundry, Toronto, the work of surveying and registering high pressure pipe lines has been undertaken. The accompanying data summarises the inspection work carried out during the year ended October 31, 1916.

Drawings and Specifications Surveyed and Registered

Boilers	97
Boiler fittings	78
Pipe lines	31
Pressure tanks	4
Superheaters	1
Drawings returned to manufacturers for correction	17
Registered boilers inspected during construction	313
Plates examined	1415
Plates rejected	16
Registered boilers inspected by Insurance companies in the United States	35
Registered boilers inspected by Insurance companies in Great Britain	4
New boilers inspected during construction for British Columbia	10
Used boilers inspected in Ontario	612
Steam drums inspected in Ontario	21
Steam plans inspected in Ontario	1
Pipe lines inspected in Ontario	4
Used boilers inspected and condemned	23
Class "A" certificates issued for new boilers	348
Class "B" certificates issued	

VOLTAGE distribution curves plotted from the bar-to-bar voltage readings taken around the commutator of an armature turning in a magnetic field will indicate the mode of the flux distribution in the air-gap. When the armature carries no current, the flux distribution will be uniform and the curve will be symmetrical on both sides of the maximum. The presence of armature current, however, will distort the flux and make its distribution non-uniform, under which condition the curve will have a sharper slope on one side of the maximum than on the other. This means that across the commutator bars that correspond to the steep slope part of the curve a much greater potential difference will be present than across the same number of bars anywhere else on the commutator. If the conditions are such as to make this discrepancy exceed a certain value, sparking or flashing, or both may result.

UNIFLOW STEAM ENGINES FOR STEEL MILLS*

By W. Trinks.**

THE trend of power supply in iron and steel plants has been to electrify every machine, up to and including the main rolls, and to concentrate the power generating apparatus in a central power house containing steam turbines in regions of cheap fuel, and gas engines with an auxiliary steam turbine for overloads, in regions of expensive fuel. Into this evolution stepped the uniflow engine, which promises or threatens (depending upon the viewpoint), to change the march of events. The iron and steel plant electrical engineer is particularly interested in this problem because a change would deeply affect his work. For him the two following possibilities are of importance:

The uniflow engine may find a place in the works power plant, or else it may drive rolling mills directly, doing away with the double conversion of mechanical into electrical power in the central station and back again into mechanical at the mill. In Germany the uniflow engine has, in many places, been used for direct rolling-mill drive in preference to electrical drives. The question to be studied is, then, what has been accomplished on this continent in the development of this type of engine, and what is the outlook for the future?

Historical Features

The history of the uniflow engine begins in 1907. In that year Professor J. Stumpf, of Charlottenburg, Germany, made his designs and applied for patents. The characteristic part of the Stumpf engine, as is perhaps already well known, is the cylinder with steam admission at the ends, discharge in the center, and steam jacketed heads, as shown in Fig. 1. The idea of steam admission at the ends in combination with central discharge is old and was patented by Todd in England in 1885, but the fact that the idea remained wholly unused until Stumpf proved that it was useful when coupled with jacketed heads and a partly jacketed barrel, credits Stumpf as the inventor of the uniflow engine from the viewpoint of the critical historian.

In 1907 Professor Stumpf clearly recognized the thermal advantages to be gained from the unidirectional flow of steam through the cylinder. In the summer of that year he fully explained his view upon the subject to the author of this paper at Charlottenburg, Germany. At that time the drawings of the experimental uniflow engines were well in hand. From 1907 to 1911 the evolution of that type of engine was limited practically to Austria and Germany. In 1911, Professor Stumpf published his well-known book on the uniflow engine, and bitter literary controversy on the merits or demerits of the Stumpf engine followed. In the same year American engineers began to take notice of the Stumpf engine and, one by one, the C. & G. Cooper Co.; the Nordberg Mfg. Co.; the Mesta Machine Co.; the Skinner Engine Co.; and the Ames Iron Works took up the building of this type. A great deal had to be learned by these firms, and some of the experience was paid for quite dearly. At the present date, the period of experimenting is practically over, and the time is ripe for a review of the situation.

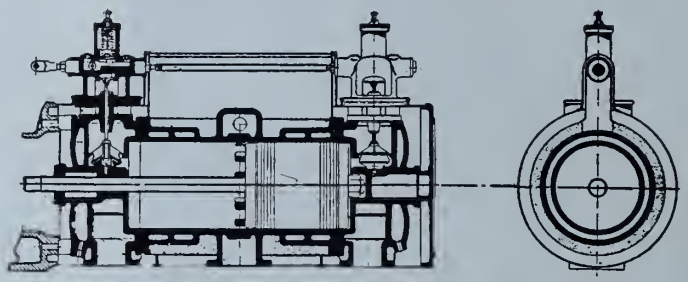


FIG. 1. LONGITUDINAL AND CROSS SECTIONS THROUGH STUMPF UNIFLOW ENGINE CYLINDER.

The principal claims for the uniflow engine are economy, simplicity, reliability and freedom from attendance. Let us consider these features in the order mentioned and then judge whether we can profitably use the Stumpf engine in our work.

In the steel works power plant this engine will have to compete with the gas engine and with the steam turbine. The gas engine was 7,500 to 9,000 British thermal units per indicated horse-power hour, whereas the uniflow engine, running condensing, uses from 11,000 to 13,500 British thermal units in the steam, and more in the fuel gas, depending upon the boiler efficiency. There is, in consequence, little hope of replacing the gas engine by the uniflow engine.

Steam Turbine Comparison

When we come to a comparison between the engine and the turbine, variation of steam pressure and of back presure makes it advisable to leave the British thermal unit basis and to introduce Rankine cycle efficiency, which means the ratio of the work actually produced from unit weight of steam to the work which could be produced by the same weight of steam passing through the Rankine cycle. From a great number of published tests made on the very best turbines, the author has formed the following averages for condensing operation:

Size of turbine, kw.....	500	1,000	2,000	5,000	10,000
Rankine cycle efficie'y	0.62	0.66	0.71	0.77	0.82

(Referred to brake h.p.)

For non-condensing operation he values are much lower.

For the Stumpf engine, data furnished by the Stumpf Uniflow Engine Co., tests made by the author, and data from Ames Iron Works and from the Cooper Co., indicate the following efficiencies:

Size of engine, kilowatts.....	300	600
From 3 lbs. per sq. in., back pressure above atmosphere down to about 23 in. vacuum.		
Efficiency:		
Saturated	71	74
100 degrees superheat	75	77
200 degrees superheat	78	79
For high vacuum (about 27½ in.):		
Saturated	58	62
100 degrees superheat	62	65
200 degrees superheat	66	68

The values may vary somewhat to one side or the other, but the general tendency is apparent. For non-condensing operation, at 100 degrees superheat, with moderate vacuum, and for sizes up to 1,000 kilowatts, the uniflow engine is more economical than the turbine. It will, therefore, find a place in comparatively small power plants, and in locations where 28 inches of vacuum or better is not obtainable. It will also be preferred for generating direct current, because turbines for the generation of direct current, when direct connected, are too slow for best economy. If they are to operate at economical speed, gears must be introduced.

*From a paper presented at the 10th annual meeting of the Association of Iron and Steel Electrical Engineers.

**Professor of Mechanical Engineering, Carnegie Institute of Technology, Pittsburgh, Pa.

Limited Field in Steel Works

Evidently, the uniflow engine will have a very limited field in the steel works power plant. Turning to the second application which interests us, namely, the driving of rolling mills, we find a changed condition. Let us for the sake of clearing up doubts, compare the uniflow engine with electric drive, and with older type of duoflow engine. In comparison with electric drive, the steam engine does away with the electric generator, the switchboard, the transmission line and the motor, but it takes undesirable piping into the mill. The elimination of the electrical part means that we must compare the Rankine cycle efficiency of the engine to the Rankine cycle efficiency of the turbine, including generator, transmission line and motor. Allowing the high efficiencies of 92 per cent. for the generator, 98 per cent. for transmission line and 92 per cent. for the motor, we must multiply the turbine efficiencies by 0.83 for comparison with the direct-connected engine.

This procedure furnishes the following:

Size of turbine, kw.	500	1,000	2,000	5,000	10,000
Rankine cycle efficiency:					
Referred to motor shaft	50	54	59	64	68
Referred to mill shaft..	47	50	55	60	64

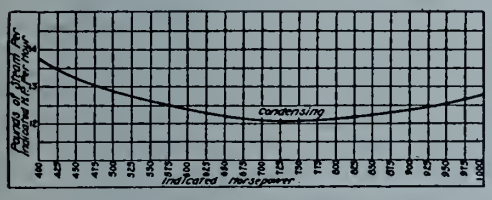

FIG. 2. WATER RATE LOAD CURVE OF ORDINARY COMPOUND ENGINE.

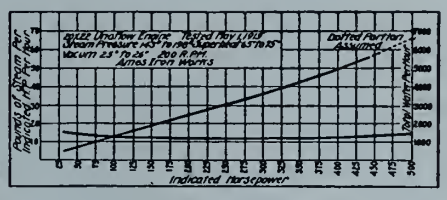

FIG. 3. WATER RATE LOAD CURVE OF UNIFLOW ENGINE.

The lower row of figures was obtained by multiplying the upper row by 0.965, this figure taking care of the efficiency of two speed reductions from the motor to the mill. A study of the resulting values shows that the uniflow engine is ahead of the electric drive, unless the steel plant is so large that turbo units of over 8,000 kilowatts capacity can be installed.

The economy of the uniflow engine compared to that of the steam-turbine-electric drive, taken by itself, is not enough better to explain why the uniflow engine should fare differently from the compound engine. The Rankine cycle efficiency of a good compound engine is practically the same as that of the uniflow engine, but there is one difference. To obtain that high efficiency, the compound engine must have a small high pressure cylinder; but the small size of the latter means a small overload capacity, and quick departure from the best efficiency for comparatively small changes of load.

Compound Engine Comparison

Fig. 2 shows the water-rate-against-load curve for a well known compound engine. Comparison of this curve with the typical water rate curve of a uniflow engine, Fig. 3, shows the difference to be very marked. Mill loads are notoriously variable, because small variations in draft, temperature of steel, velocity of rolling, etc., cause disproportionately great changes in resistance. It is not possible to exactly foretell what the load will be, and it is therefore of the utmost importance to secure a drive which permits over or underloading without serious change of economy. The uniflow engine, and the electric motor hitched to a large central station, both fill this requirement.

The old type simple duoflow engine, the old reliable standby of the rolling mill for over 50 years, cannot be considered here. It is so wasteful, that its low price is more than offset by increased cost of boiler house equipment, not to mention the continuous cost of fuel and water. It retained its place in the mill a long time, due to its simplicity, but was replaced here and there by the compound engine on account of its wastefulness. The uniflow engine combines the simplicity and overload capacity of the simple engine with the economy of the compound engine; it has the added advantages that its overload capacity is even greater than that of the simple engine and its economy is sustained over a greater range of load. Finally, it has very few moving parts and takes up much less floor space than the compound engine.

Variation in back pressure naturally affects the operation of the uniflow engine. However, the vacuum may, with 4 per cent. clearance, vary from 19 to 27 inches of mercury without unduly high compression, or pounding, due to lack of compression. If the vacuum fails altogether, clearance is automatically added, to keep the compression down.

Uniflow Engine Development

A great deal has been written on the reasons for the economy of the uniflow engine; nevertheless the author will try to present the underlying facts again in as concise form as possible. The secret of the economy of the uniflow engine lies principally in reduction of internal cylinder condensation. In the duoflow single expansion engine, cylinder condensation is so great, that a very great free expansion loss must be allowed for best economy (or rather for minimum wastefulness). In the compound and triple expansion engine, cylinder condensation is reduced so that the free expansion loss can also be reduced, but mechanical losses due to the passing of the steam through so many valves becomes great. In the duoflow engine, cylinder head, cylinder barrel and piston head are alternately heated and cooled by live steam and exhaust steam sweeping over them and wiping heat "on and off".

In the uniflow engine, only the piston head has heat wiped off during the extremely short period of exhaust, the steam near the place of entrance of live steam being at rest like the fixed end of an expanding coiled spring during exhaust, and like that of a compression spring during compression. Besides, the cylinder head and part of the barrel are steam jacketed, and steam jacketed surfaces are cooled very little by stagnant steam. It may be remarked again that the mere provision of a central exhaust does not bring about a successful uniflow engine; the steam jacketing of the heads and of part of the barrel must go with it, to produce the thermodynamic superiority over the duoflow engine.

In the duoflow engine, long compression means increased steam consumption, principally, because the steam temperature exceeds the cylinder (or piston) wall temperature a longer time than it would with shorter compression. In the Stumpf uniflow engine the steam which is being compressed is in contact with progressively hotter surfaces, with the exception of that of the piston, and the steam temperature never rises very much above the wall temperature.

The second reason for the economy of the uniflow engine lies in the enforced or compulsory tightness Steam cannot leak from the live steam space to the exhaust. If the inlet valves are leaky to any exent, the compression rises so quickly that the inlet valves clatter and give notice to the engineer that something is wrong.

In comparing test data with calculation results, I have obtained very good results by using Heck's formula for the internal condensation or missing quantity, but I substitute instead of his constant C the value

$$C - \sqrt{\frac{\text{°F. superheat}}{4{,}500}}$$ for duoflow engines, and $$0.45\ C - \sqrt{\frac{\text{°F. superheat}}{10{,}000}}$$ for uniflow engines.

Uniflow Engine Economy

The development of the uniflow engine in the United States has been slow, probably because it did not fit into the general trend of changing from reciprocating to rotating machinery, and because it is of foreign origin. It began in a small way in 1912. The C & G. Cooper Co., Mount Vernon, O.; the Nordberg Co., Milwaukee, Wis., and the Mesta Machine Co., Pittsburgh, began almost simultaneously to build experimental engines . All three firms moved cautiously and equipped their engines with Corliss gear. All three found out that the Corliss releasing gear, in its usual form, is not ideal for

the uniflow engine, because the cut-off is so short, because modern plants carry high pressure with superheat, and because the pressure drops so fast after cut-off, that the valve becomes unbalanced too quickly for the ordinary design and size of vacuum pot. In consequence, the Mesta Co., and the Nordberg Co. switched over to poppet valve gears, while the Cooper Co. adapted its Corliss gear and vacuum pot to the new conditions.

The smaller sizes of uniflow engines have been developed by the Ames Iron Works, Oswego, N.Y., and by the Skinner Engine Co., Erie, Pa. The Ames Iron Works, from the very beginning, adopted poppet valve steam distribution, with shaft governor drive. This design is very well adapted for small engines up to 400 or 500 horsepower, and is very successful. For larger sizes and high steam temperature it is not so well adapted, because the difference in expansion between the valve rod and the cylinder becomes too great and disturbs steam distribution. For poppet valve engines above 500 horsepower the lay shaft drive is preferable.

In the sizes built by the Ames Iron Works, a self supporting piston, guided at the crank end only, is said to be satisfactory. In larger sizes this same design leads to a great deal of trouble. On account of difference in expansion, the piston must fit very loosely in the cylinder. The guiding of the piston by the crosshead is very imperfect. The piston, therefore, wobbles around in the cylinder, riding now on one spot, then on another, never wearing itself in, but rapidly wearing itself out. In large engines of German design, a tail rod guide has been provided, not so much for the purpose of carrying the piston, but mainly for the purpose of guiding it, so that it will always touch the cylinder in a large surface. American engineers have gone one step further and have made the piston rod strong enough to carry the piston.

Early Troubles

The early part of the practical development was thorny. Cracked cylinders, heads and bed plates caused trouble; valve gear troubles and regulation troubles had to be overcome, pistons and cylinders wore too rapidly; but the problems have all been solved and the future promises to be free from any obstacles whatsoever. Whatever troubles were experienced, naturally appeared more forcefully in the larger sizes, with the result that the smaller sizes, developed by the Ames Iron Works and the Skinner Engine Co., have made more progress in numbers than the larger sizes. It can safely be said that the uniflow engine to-day is as reliable as the simplest engine of the duoflow type. Additional steam consumption charts may be appreciated. To the scientific engineer they do not mean as much as Rankine cycle efficiencies, but habit has led many of us to think in pounds of steam per horsepower-hour. Consequently, Fig. 3 is given showing steam consumption of various types and sizes of uniflow engines.

PIPING FOR STEAM GENERATING PLANTS

It is of particular interest, in connection with this article, to note that a separator or receiver of approved type and of suitable size, installed in the pipe line as near the engine as possible, decreases or entirely prevents vibrations that might otherwise be transmitted to the steam piping by the continued opening and closing of the engine valves—which tends to cause pulsations of steam in the pipes. The steam in the receiver acts as a cushion to absorb the shocks caused by the quick cut-off in the steam chest of the engine.

Vibration in steam pipe lines is not only a source of annoyance, says the *Travelers' Standard*, but it is also positively dangerous, provided it is of sufficient intensity and is continued during a considerable period. Given the proper conditions, the pipes may be loosened from their supports by the vibration, the supports themselves may gradually pull away from the walls or beams to which they are secured, and other damage may be caused.

Causes of Vibration

The operation of the engine valves is not the only cause of vibration in the pipe lines. Vibration may also be due to the sudden changing of the direction of the steam flow where short-turn tees and elbows occur, and by variations in the velocity of the steam flow in different parts of the piping system. Steam boilers also, may, under certain conditions, transmit vibration to the piping which is connected to them. When the plant is operating at its fullest capacity, or with an overload, and the steam space in the boilers is insufficient, the pressure is quite likely to diminish rapidly. This will cause the water in the boilers to boil and bubble violently, with the result that the boilers will vibrate considerably.

If the engine-governor or the valve mechanism is out of order or improperly adjusted, the engine may be caused to vibrate, and the vibrations may be transmitted to the piping. It has also been observed that vibration and the accompanying strains are specially pronounced at intervals, in plants where several high speed engines are in operation at the same time. This may cause the pipes to vibrate in unison a part of the time; but the synchronism is likely to fail and each pipe will then vibrate independently of the others.

Vibration Prevention

After the cause of vibration has been determined in any particular case, a cure for the trouble will usually suggest itself. In installing a system of steam pipes, it will save much subsequent annoyance, expense, and perhaps danger to take all possible precautions against the propagation and transmission of vibrations which may in any way be due to the engines, boilers, or piping. A suitable separator or receiver should be provided and installed as near the engine throttle as possible—one having a capacity three or four times that of the high-pressure cylinder of the engine being not any too large. The pipes should be supported and anchored properly, not losing sight of the fact, however, that a certain amount of flexibility is essential to guard against dangerous contraction and expansion strains (which will be referred to later), caused by changes in temperature; long-turn bends should be used wherever possible; and the entire system should be proportioned so as to make the velocity of the steam as nearly uniform as possible in all the pipes.

Well designed boilers of ample capacity are requisite in order to secure satisfactory results, and the necessity for forcing them should be avoided. Engine-governors, valves, and other essential parts should be kept properly adjusted, not only to prevent vibration, but also to guard against troubles of other kinds which would be almost certain to result from neglect in this respect.

Expansion and Contraction

Pipes in a steam piping system expand as they are heated by the entering steam, and contract as the temperature falls when the steam is shut off. The co-efficient of expansion is so small that the increase in the circumference of a pipe due to the application of heat is of no consequence. In a large plant, however, there may be pipe lines several hundred feet in length, and then the effect of alternate expansion and contraction throughout the length of the pipe may have an important bearing on the safety and economy of the plant. Unless proper means are adopted to relieve the strains caused in this way, the pipe joints are likely to open and leak, fittings may be broken, or the pipe itself may rupture at its weakest point.

These dangers may be eliminated by firmly anchoring the pipe at a suitable number of points, the number depending upon the length of the pipe. If the pipe is a comparatively short one (say up to 50 feet or thereabouts), it will usually be sufficient to anchor it in the middle of its length, allowing the two ends to expand away from the anchor. This method is not suitable for longer pipes, however, and as previously stated, several anchorage points must be selected, the number depending upon the length of the pipe. The anchors and supports for the pipes should be located as near as possible to the flanges which join the various sections of the pipe line, so that those parts will not be subjected to undue stresses. The points where the pipes connect to boilers, engines, and other apparatus should also be protected as adequately as possible against expansion and contraction strains.

The expansive force of heat acting upon a steam pipe is practically irresistible and it is therefore necessary to make some special provision to care for the expansion of the section of pipe between the two points at which it is se-

cured. This is usually best accomplished by the use of expansion loops or bends. Whenever possible, the bend should be installed in a horizontal position—that is, in the same plane as the main pipe; but if for lack of room or for any other reason it is necessary to place it with the loop or bend extending upward from the main pipe, a drip should be connected to the main pipe on each side of the expansion bend. These expansion bends should have a radius not less than six times the diameter of the pipe, and the flexibility of them will be increased if the radius is made still larger. Right-angle pipe bends should be used wherever possible in place of elbows, to aid still further in eliminating expansion and contraction strains.

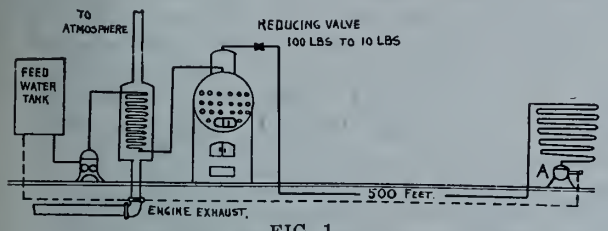

FIG. 1.

Unless great care is taken when installing pipe lines it may be necessary to force some of the pipes into position to make the joints. Strains caused in this way should be avoided, because they are likely to be magnified when the pipes are heated, and to cause serious trouble. The workmanship should be of the best, and the pipes and fittings should be of the highest quality and carefully selected. Pipes and fittings having crooked or defective threads, and pipes with improperly fitted flanges should be discarded.

OTHERS' MISTAKES AND MY OWN

By R. Manly Orr.

SOME time ago an incident occurred which impressed on me the necessity of every engineer understanding the why and wherefore of the different jobs he is called on to perform. It occurred at a certain plant of which a friend of the writer has charge, a diagrammatic layout being shown in Fig. 1.

A new manager arrived on the scene one day, and happening to see trap A discharging very hot water to the atmosphere, ordered it to be connected back to the boiler-feed tank, as indicated by dotted line. The engineer, eager to carry out the orders of the boss and feeling half guilty at not having suggested the saving himself, set diligently to work, and when the writer happened to look in one day, had dug a long trench across the mill yard, cut through a plank roadway, and laid out several bundles of 1 in. galvanized pipe ready for connecting up.

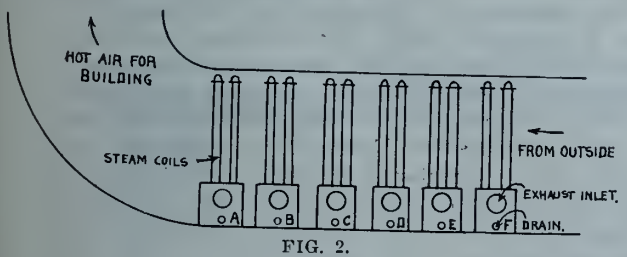

FIG. 2.

"What are you doing?" I asked. He told me.

"Water costs you nothing but pumping here. What's the idea?" I rejoined.

"The heat," he replied. "The boss says all that heat running to waste represents dollars in fuel, and he wants to save it by putting it back into the feed water. I tell you he's a close one."

Not Time to Laugh

I wanted to laugh, but I remembered some of my own fool mistakes, so looked serious and interested instead, finally remarking: "That won't make the water from the heater to the boiler any hotter, will it?"

"N—no," he replied, "but it will save-s-some exhaust steam."

"I see," said I, slowly. "It will take less exhaust steam to heat the feed water and give you so much more exhaust to shoot up into the air."

He looked at me a moment and then burst out laughing—and I helped.

The job was finished and put into service and my friend told me afterward that the boss came in several times and put his hand on the suction pipe of the pump, which was hotter than before, remarking, "That's fine."

Having admitted making mistakes himself, the writer will at least mention one.

At one time the plant of which he had charge was heated by exhaust steam, the entire amount available being passed through the coils shown in Fig. 2. During the coldest part of winter, the supply of exhaust steam was not sufficient to keep the building warm, so the superintendent ordered two of the banks of coils to be changed from exhaust to live steam. The writer thereupon put banks E and F on live steam and thought no more about it until some months later when studying a condenser catalogue, the "counter-current" principle was brought to his notice, causing him to realize his error in putting live steam into coils E and F instead of A and B. The connection was immediately made, resulting in hotter air with less live steam.

AUTOMATIC BOILER FEED-WATER REGULATORS

IN order to have satisfactory and safe operation of a steam boiler, it is absolutely necessary that the water level be maintained within certain limits. If it be possible to accomplish this by means of some reliable mechanical device, instead of relying upon the constant attention of a fireman or water-tender, who is human, and therefore liable to make mistakes, the advantage is apparent, from the point of view both of safety and of economy of labor. As a result, a number of different devices have been developed, whose object is to control automatically the flow of feed water into a boiler, so that the water level will be maintained within certain predetermined limits. These devices are called automatic boiler feed-water regulators and they seem to have a very high degree of reliability. Many advantages are claimed for them besides those already indicated, chief among which is increased boiler efficiency due to their use.

If, in addition to the automatic feed-water regulator a high-and-low-water alarm is installed, the danger of high or low water is reduced to a minimum, for, in case the automatic regulator fails to operate properly, the fireman's attention is called to that fact by the high-and-low-water alarm, and he can then control the feed by hand until the trouble with the regulator has been overcome.

INTERNAL COMBUSTION ENGINE LUBRICATION

IN the vertical type of internal combustion engine, it is absolutely essential, in order to secure a distribution of the lubricant around the cylinder bore, to supply the oil through a number of feeds, as many as four per cylinder on the smallest sizes and more on larger diameters. A horizontal cylinder, on the other hand, even of the largest size that is practicable to build, can be effectively lubricated over its whole surface from a single feed on the upper side. Gravity helps to distribute the oil.

In any internal-combustion engine, some of the lubricating oil is carbonized. In a vertical engine this carbon tends to work down past the piston, fouling the rings and dropping into the crank pit, where it becomes mixed with the bearing oil. In the horizontal type, much of this carbon is pushed into the counterbore, whence it can be removed through a blow-off valve in the bottom of the cylinder. Such portion as works past the piston can be caught in the frame and prevented from mixing with the bearing lubricating oil. Even the main bearings in a horizontal engine are more effectively lubricated. During the working stroke, when the pressures are highest, the main shaft is partly lifted from the bottom shell, allowing the lubricant to fill the space; again, on the two idle strokes, the exhaust and inlet, inertia effects tend to bring the shaft first against one side of the bearing, then against the other, thus effecting a very thorough distribution of the oil.

MORE EFFORT, MORE MEN, MORE MONEY.

IF there is one thing more than another that the recent peace scare has demonstrated, it is the fact of our being in this war to the "knock out" stage. Beyond the confines of the stock market, where expediency, imagination, or reality, stand ever ready either to woo or create opportunity, little excitement and probably still less business dislocation resulted from the now silenced dual-source peace proposals with their "soft pedal" heralding. Renewed and still more forceful expression has been given of the determination of Britain and her Allies to prosecute the war to its logical conclusion, and in this respect the very untimeliness of the peace suggestions have not been without a salutary effect. As we see it, the Dove of Peace—were that the fair bird or another in its borrowed plumes—has tucked its head under its wing for many months to come, under which circumstances, munitions, men, and money, to the limit of our capacity and resources must needs be our New Year programme. Our Imperial Munitions Board, our National Service Commission, and our Patriotic Fund Executive, all war-created organizations, are more intensely than ever war-in-earnest. Coupled with the "Thrift Campaign" now been planned by our Minister of Finance, Sir Thomas White, it is abundantly evident that our efforts and responsibilities are primarily those of war concern, and, therefore, wasted if otherwise directed and evaded. Much is expected of us during the coming year and largely dependent on our measure of response—ourselves and our substance, will the ushering in of a peace worth-while be hastened.

PASSING OF A LEADING CANADIAN MANUFACTURER

IN the death of Hugh McCulloch, president of the Goldie & McCulloch Co., who passed away at his home, Sorn House, on January 8, Galt has lost one of her leading and most highly esteemed citizens. Mr. McCulloch, who was in his 61st year, was born in Galt on September 7, 1856. He received his education at the Whitby Grammar School and Upper Canada College, on completion of which he served an apprenticeship in the Goldie & McCulloch shops, his father, Hugh McCulloch, sen., being then president of the company. Practically his whole life has been spent in furthering the interests of the firm in which he was a member, and the industrial interests of the community in which he lived. When the company was incorporated in 1891, and took over the business of the firm of Goldie & McCulloch, he was appointed secretary-treasurer, which position he held until elected vice-president in 1898, assuming the presidency on the death of his father in September, 1910. Mr. McCulloch was closely associated with various other manufacturing concerns in Galt, having been at the time of his death vice-president of the Galt Malleable Iron Co., also of the Galt Art Metal Co., a director of the Gore Mutual Fire Insurance Co., also for many years a director of the Galt Gas Light Co. In religion Mr. McCulloch was an honored member of Knox Presbyterian Church. His principal amusements were fishing, golf and motoring. Sorn House, his home, constitutes in itself and location one of Galt's beauty spots. There survive him a sorrowing wife, one brother, R. O. McCulloch, of Galt, and one sister, Mrs. Chas. A. Shearson, of Toronto. The funeral, which took place at Galt on Wednesday, January 10, was very largely attended, the number of local mourners being materially supplemented by friends and business associates from other places.

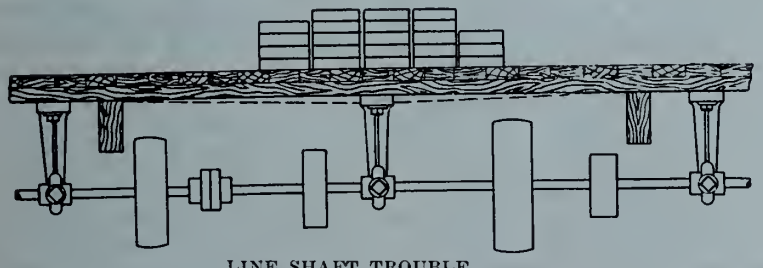
The Operators' Point of View

LINE SHAFT TROUBLE

By J. H. R.

AMONG the many problems that power users are required to solve, those arising from transmission are probably the most numerous. No one application is identical with another, and local conditions make it imperative that each installation, or the solution of trouble arising from unknown causes, must be dealt with on its own merits. Previous experience is often a guide to the difficulties of the moment, but unless a careful study is also made of the local surroundings, it is not to be expected that the results obtained will be entirely satisfactory.

Some time ago, a certain shop was confronted with considerable trouble on a portion of a line shaft, that taxed the patience of the foreman for quite a long period. The accompanying line drawing illustrates roughly the arrangement of the hangers and shafting. As shown, the centre hanger came about midway between two joists, the next on either side being located on the other side of the joists. On numerous occasions the centre bearing would become heated and trouble would develop in the shaft coupling. This experience was not continuous, only taking place at irregular intervals. Several efforts were made to remedy the trouble by lining up the shafting, which on each occasion required adjustment. However, the source was discovered one day when the foreman was on the floor above. He noticed a large pile of cased tin in the centre of the floor and the vibration that developed when another case was added to the pile. Upon investigation, it was found that this lot of tin, weighing over two tons, was placed directly over the hanger



LINE SHAFT TROUBLE

which was giving trouble. Being an old building, this floor was not intended to support any great weight upon a small area. The result in this instance was a depression in the floor, which, being transmitted to the hanger, caused a bend in the shaft and hence originated the trouble. The removal of the cases to a more suitable position and the exercise of care in the subsequent location of all heavy loads effected an immediate permanent cure.

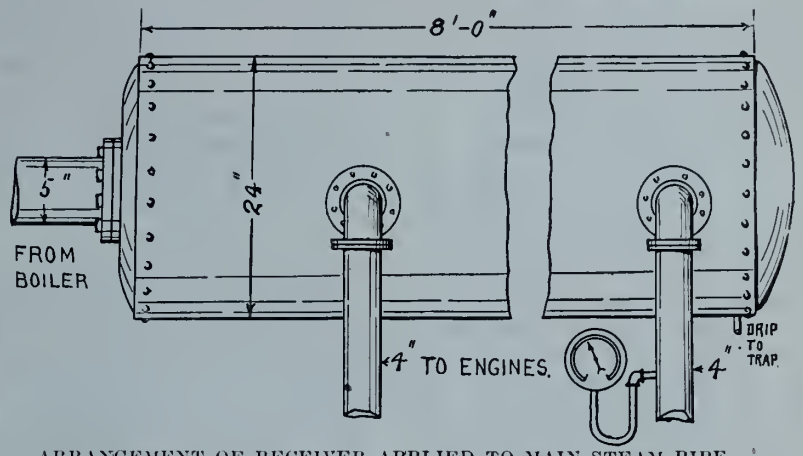
STEAM TRAP TROUBLE

By J. Ford.

IN a large institution known to the writer the exhaust steam from the engines was used for heating water for baths, etc., the water of condensation from the heaters being returned to the hot well by a Bundy steam trap with 1½ in. inlet and outlet. The trap was an old one which had been used for many years previously on a hot water system, having been removed latterly because it did not appear to be working in a satisfactory manner. It appeared O.K. as far as the writer could judge, so it was installed as stated.

When all connections were made and the system started to work, the trap made a few half-hearted efforts and then quit operations altogether. The packing was examined in case of defects, and replaced with new, but the trap continued obdurate. The nuts on the high pressure steam valve were reset without any greater success, and a weighted check valve was also placed on the outlet side on the chance of the trouble being there as it was noticed that the receiving chamber would remain in the lower position, at the same time allowing high pressure steam to blow through continually.

The chamber was thereupon removed and examination disclosed that at some time in the past the 1 in. tube had broken off inside the chamber. A new tube was inserted and the trap connected up again when it started off without further trouble.



ARRANGEMENT OF RECEIVER APPLIED TO MAIN STEAM PIPE.

OVERCOMING TROUBLE WITH STEAM PIPE

by J. James

THE accompanying sketch shows how a case of engine trouble due to defective piping arangement was remedied. A 5 in. main steam pipe supplied steam for two high speed engines direct connected to 300 amp. D.C. generators, the branch steam pipes to the engines being 4 in. dia. When the load was 280 amps. on each generator, the engines would begin to race. The valves were examined and found O.K.; also the governors, and all other parts. A steam gauge was then connected, and when the load reached 280 amps. each, the hand would begin to vibrate considerably.

The conclusion arrived at was that the engines were not getting enough steam.

The 5-in. pipe was disconnected and a receiver installed as shown, which overcame the trouble, all pipes and receiver being well covered to prevent condensation as far as possible.

A FUEL OIL INSTALLATION.

by A. F. Menzies

THE reference to a fuel oil installation in the "Question and Answer" section of your November issue prompts me to give the following description of a mechanical atomisation system installed in connection with a pair of Scotch type marine boilers, and which gave perfect satisfaction. As the job was afloat and in salt water it was considered out of the question to use a steam atomisation system, even though it would have been less expensive to install. The oil was carried in the fore peak tank and a 4 in. suction pipe led from its after bulkhead to the stokehold. On account of the viscosity of the oil, large suction pipes are necessary in order to reduce the velocity and consequently the friction. The oil was pumped by two 3½ in. x 2½ in. x 4 in. steam driven duplex pumps, which, on account of the deleterious action of the oil on rubber, etc., were specified to be fitted with brass rings and valves in the oil end, and to be packed with asbestos. Immediately in front of where the suction pipe entered the pumps, a twin suction strainer was installed, arranged to be cleaned out while steaming.

Steam Supply to Pumps

The steam supply to the pumps was regulated by the oil pressure in the discharge line, the regulating valves being set to the desired pressure, which is usually found by trial. In this particular instance, a pressure of 90 lbs. per sq. in. was found suitable, when using a No. 3 Dahl tip. On leaving the pumps, the oil was piped to a pair of live steam heaters, consisting of a cast iron shell in which a coil of pipe was placed. The oil passed inside the pipe, while steam was admitted to the shell, the temperature of the oil being raised to from 225 to 250 degs. F. A high pressure steam thermometer was installed in the heater outlet in order that the temperature could be ascertained. In a by pass between the pumps and the heater, a Worthington oil meter was installed. To remove any fine particles of grit or pipe scale from the oil, a pair of discharge strainers were installed between the heaters and the furnaces, and as the oil is of much lower viscosity when heated, a strainer of fine mesh can be used on the discharge line.

The header from which the burners were fed was led across the front of the boilers below the furnaces, branches being taken to each burner. The end of the header was connected to the suction pipe in order that a circulation of oil could be obtained on starting up, thus providing heated oil at the burners. The burners themselves, one for each furnace, consisted of a piece of pipe with a special tip at one end having spiral passages leading to a circular hole in the centre.

Fire Regulation

The size of the fire could be regulated by varying the pressure of the oil. If the desired results could not be obtained within the suitable range of pressures, it was a very simple matter to subsitute a tip with a larger or smaller hole as the case required. With the beforementioned pressure, a tip with a 1-32 in. hole gave very good results. The furnaces were 37 inches in diameter. The outer end of the burner had a special union connection to the oil pipe branch, and could be removed by the slackening of one set screw. If a burner did not work satisfactorily or got choked up, it was the work of less than half a minute to remove it and substitute a spare one. Surrounding the burner tip was a hollow cast iron cone with the apex pointing to the furnace front. The cone was carried on a pipe through which the burner passed and was made conveniently adjustable, in and out. Its correct adjustment was an important factor in smokeless combustion.

The fire bars, bearers and all brick work, were removed from the furnace and new fronts were installed. The fronts were ⅜ in. plate and had hinged air doors above and below the burners. Commencing at the front, the furnace was lined with firebrick for about three feet, in order to give protection from the intense heat. A considerable reduction in the consumption of fuel was obtained by the use of spiral retarders in the tubes. It will be noted in this installation that all important items, pumps, strainers and heaters, were installed in duplicate, the object to avoid a shut down. If this precaution were not considered necessary, a single pump and heater could be used. Strainers should, however, be duplicated. The apparatus for this installation was secured to the stokehold bulkhead, and was so connected up with unions that any piece could be undone and removed for convenient overhaul.

Oil Burning Regulations

Some of the more important regulations which have to be observed in connection with an oil burning system coming under the control of the Canadian Steamboat Inspection are as follows: Storage tanks must be absolutely tight and constructed of not less than ¼ in. plate. The stop valve on the tank end of the suction pipe must be located inside the tank, and the spindle extended through a stuffing-box on the tank top. The idea of this is to prevent leakage from the valve spindle draining into the bilges. Proper ventilation must be provided for the tank. The exhaust steam from the oil heater must not be piped to the condenser; but must be drained overboard or into the bilges.

In any oil installation, ground joint union and regrinding valves are an absolute necessity. After installation and before oil is admitted to the pipes they should have all dirt, pipe scale, etc., blown out with compressed air or steam. It is a comparatively easy matter to clean the pipes when first put up, but it is a different story after they have been filled with sticky oil.

The Economy Feature

As regards the economy of using liquid instead of solid fuel, this simply resolves itself into a question of their relative costs. On the Pacific Coast, where coal contains between 12,000 and 13,000 B.t.u. per lb., and the grade of oil sold for fuel purposes runs from 19,000 to 20,000 B.t.u. a ton of coal is usually regarded as equivalent to from 3½ to 4 barrels of oil. Oil can be wastefully fired just as easily as coal, if not, more so, as there is less labour involved for the fireman if he is economical with his coal. There is the saving of labour handling to be figured to the advantage of liquid fuel. In this particular installation no exact comparison was possible.

All the special apparatus used on this installation was manufactured by the Union Iron Works, of San Francisco, Cal., under the Dahl patents. The work of installation was carried out by the Wallace Ship Yards Ltd. of North Vancouver, B.C. Lunkenheimer regrinding valves, and Dart unions were used throughout.

BUILDING VERSUS BORROWING FORCE-PUMPS

By J. E. McCormack.

THE coming into force of clause 5, sec. 57 of the revised Provincial (Ont.) laws relating to boiler inspection has resulted in an epidemic of force-pump borrowing in many localities, which can scarcely be profitable in many instances where express charges have to be paid both ways, especially when one considers how readily a pump can be constructed out of steam pipe and fittings.

The significance of the force pump question is more fully realized when reference is made to the itemized record of inspections as given in the last annual report of the Factory Inspection Branch for the Province of Ontario, in which the number of localities in which there was only one inspection was 25 per cent., and those with only 2, 3 or 4 inspections about another 25 per cent. Additional force being lent to this statement when it is remembered that many of the plants in towns and cities have insured boilers, or operate on electricity or gas, while the isolated plants are invariably steam-driven.

Force-pump Construction

As a result of the writer's desire to possess his own force pump and avoid the annual borrowing, a home-made affair was constructed which in spite of simplicity and low cost performed the work satisfactorily. Investigation of a certain scrap heap resulted in the discovery of two old style check valves, which had been replaced by renewable face valves. These were re-ground, rendering them serviceable for a time and were connected together by two 1-in. nipples and a tee. A plunger was made by using a piece of ½-in. pipe, 28 in. long, while the cylinder was made of 1-in. pipe, 24 in. long, with a 1¼-in. x 1-in. bushing, and a 1¼-in. cap on one

end, the cap being drilled with a 7/8-in. hole. The 1/2-in. pipe was now passed through the 1¼-in. cap, and a 1/2-in. cap placed on the inner end, the burr on the ends of the 1-in. pipe being previously removed to clear the 1/2-in. cap. A tee was now put on the outer end of the 1/2-in. pipe, capped nipples of suitable length being inserted in each side of the tee to form handles, after which the 1-in. pipe was screwed home in the tee between the two check valves. See Fig. 1.

Packing the Plunger

The 1¼-in. cap was removed and some candle wick wound in the space between the bushing and the plunger, while good piston rod packing was placed inside the 1¼-in. cap, which was then replaced. Boiler connections were now required to complete the apparatus, and for this purpose a union or pair of pipe flanges is most convenient.

The actual material used was according to the following list:—1 piece 1/2-in. pipe 28 in. long, to be carefully handled in the vise to avoid damage while threading; 1 piece 1-in. pipe 24 in. long; 2 1-in. nipples; 2, 1/2-in. nipples; 2 check-valves; 1, 1-in. tee; 1, 1/2-in. tee; 3, 1/2-in. caps, 1 will do; 1, 1¼-in. cap; 1, 1¼ x 1-in. bushing; some candlewick and piston rod packing. If purchasing new check valves, the writer would have the suction check the same size as the plunger, with the delivery check a size smaller; this would call for a change of the nipples as listed above, with an extra bushing also. By having the plunger 4 in. longer than the cylinder, the chances of jamming one's fingers while working are removed.

Pressure Capacity

With a plunger 1/2 in. dia., and little or no leakage, one man could put on a

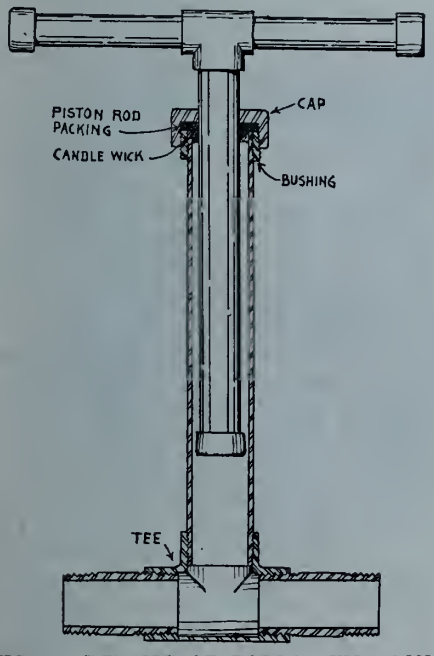


FIG. 1. DETAILS OF FORCE PUMP CONSTRUCTION.

pressure of 130 to 140 lbs. per sq. in. and with a 3/8 in. dia. plunger, 160 lbs. per sq. in. could be obtained; where there was considerable leakage, however, as through a worn safety valve or throttle, the amount of water handled was too limited. To meet such a case, should it arise, there was provided as extra equipment a piece of 1¼-in. pipe, 25 in. long, for the cylinder; 1 piece 3/4-in pipe 30 in. long for plunger, with 3/4-in. cap on one end and a tee on the other; 1, 1½ x 1¼-in. bushing with 1½-in. cap (drilled) for stuffing-box; and 1, 1¼-in.

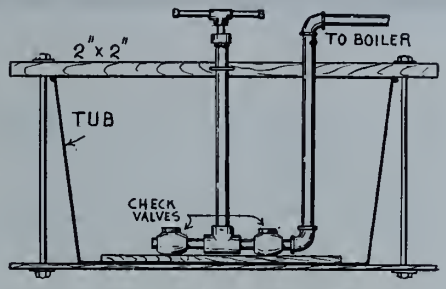

FIG. 2. ARRANGEMENT OF FORCE PUMP FOR TESTING BOILERS.

tee and 2, 1¼ x 1 in. bushings for connecting the 1¼-in. cylinder to the same old check valves. This gave a certain amount of adaptability to circumstances and by using a piece of broom handle in the plunger tee, two men could take hold to operate. It was not found necessary to finish the plunger any more carefully than by filing off the most prominent rough spots, the fill being mostly used lengthwise of the pipe.

Arrangements for Use

The success attending the use of apparatus of this class is largely due to the fact that—unlike a steam cylinder—a water cylinder does not necessarily require a snugly fitting piston, so long as the water flows to the inlet, and there is no leakage at the valves or stuffing box. In using the outfit, a tub was secured and a piece of board fitted inside to protect the bottom and another piece across the outside, after which a 2 in. square piece was placed across the top and tied down to the bottom board with rods. The pump was now placed on the inside board and the upper end of cylinder secured to the cross-piece with a U-bolt. A street elbow in the high pressure check and a piece of pipe with another elbow allowed boiler connections to be made above water level; and by filling the tub with water, the pump held firmly with a water supply free from air leaks during the suction stroke except what little might get in through the stuffing-box, which, however, was almost watertight during the pressure stroke.

Other People's Efforts

The above efforts have been so successful, that instead of borrowing, the writer is now lending his pump to others and so far no complaints have been heard regarding its work. As offering a comparison with the foregoing apparatus, the writer remembers one party who had a boiler-feed pump which was so designed that it could be partially dismantled and then operated by means of a hand lever; it was used when required for boiler testing purposes when it was operated by four men at the ends of a 2 x 4 in. scantling. After trying in vain to get up sufficient pressure for testing purposes, he borrowed one of the pumps described herein. Another man claims that he can, and is going to make a force pump that he can take apart and carry in his grip, giving as his reason the fact that he does considerable work among outfits which work intermittently and that he is frequently obliged to inspect the boiler before commencing operations. He has a wide acquaintance and claims to be able to keep in work most of the time by keeping in touch with the various employers on his "route," few of whom own suitable force pumps.

HUMAN FACTOR IN THE WORK-SHOP

By J. Wright.

PRESENT-DAY competition has become so keen that the scientific and mechanical world are working at high pressure devising ways and means to increase the quality and quantity of manufacturing output at a minimum expenditure, both of money and material. It is only within the past few years, however, that any great amount of consideration has been given the general betterment of conditions under which employees operate in industrial establishments. It is encouraging, however, to note that the value of the human element is being more and more appreciated at its true value.

Examples might be cited where material gain was falsely considered of more importance than the health or welfare of the employee. Some years ago on a certain machine, the "boss" had considerable difficulty in keeping it in continual operation owing to the irregular attendance of the operator, who was absent quite often as a result of contracting heavy colds, due to the draught created by the opening of a nearby door. A screen was suggested, but nothing was done until the season arrived when artificial light was necessary. The open gas jet could not protest against the draught, but, as the light was essential, a screen was erected to "protect the light," and thus provide a better opportunity for the man to work.

On another occasion the superintendent was showing a visitor about the works, and happened through the galvanizing department at a time when some tanks were being supplied with fresh acid. The visitor lost no time in seeking the freer atmosphere of the adjoining room, remarking to his host that he would not work in such a place for $20 a day. The boss replied that "the men did not mind it; in fact, they actually eat the stuff." This was probably true, and they were doing it for much less than $20 a day, or even a week, while in reality the fumes from the acid were slowly consuming them as the days rolled by. However, not long after this visit facilities were provided to aid in carrying off the poisonous fumes and permitting healthier working conditions for the employees.

Operators' Instruction Course

CONCERNING INDICATOR DIAGRAMS—IV.

IN our December issue, the features of the steam expansion curve, cylinder clearance, characteristic cards from a variety type engine, also the occurrence and causes of faulty diagrams,

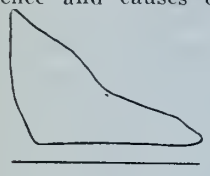

FIG. 14.

FIG. 15.

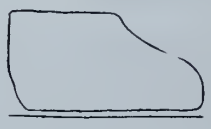

FIG. 16.

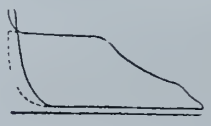

FIG. 17.

were dealt with at some length. A further discussion of the latter constitutes the introductory section of the present article, followed by an extended reference to the procedure followed in indicating compound engines, and combining the resultant diagrams.

Faulty Diagrams

Steam Throttled During Admission, Fig. 14.—When steam is throttled during admission, the steam line drops instead of being horizontal, indicating that the steam port is not open for a sufficient time.

Cut-off Too Early, Fig. 15.—The steam expands until its pressure is less than the back pressure, and the expansion line crosses the back pressure line to form the loop (g). This is frequently found on automatic cut-off engines working on light load. On such engines it is caused by too high steam pressure and wastes steam for the amount of work done, besides causing reversal of pressure and pounding. It cannot be remedied by re-setting the valve. Steam must be throttled, the back pressure lowered by running condensing, or the engine run slower. The dotted line shows the result of slowing down the engine and cutting off later. This diagram shows also the result of too early compression. The steam is compressed in the clearance

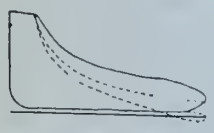

FIG. 18.

FIG. 19.

space until the pressure rises above that in the steam chest.

Cut-off Too Late, Fig. 16.—This is characterized by a high pressure at release, and means a big waste of steam due to its inability to do more work by expansion before the exhaust opens. The boiler pressure should be raised so that a diagram of equal area may be obtained with an earlier cut-off, or the revolutions of the engine increased, and the cut-off made earlier.

Compression Too Early, Fig. 17.—When compression takes place too early the pressure in cylinder rises above that in the steam chest, and may cause chattering of the valve, pounding and heating, in addition to reducing the effective work of the steam. The dotted area plus the loop indicate the additional work obtained by setting the valves for proper compression. A similar loop may be caused by the absence of load on the steam valve, but when this fault occurs the loop comes to a sharp point at the top.

Leaks Indicated by the Expansion Line, Fig. 18.—If the expansion line is noticeably above the theoretical adiabatic expansion line, steam enters the cylinder through a leaky valve after cut-off. If the expansion line falls below the theoretical, steam leaks past the piston, or gets out through a leaky exhaust valve.

Leaks Indicated by Compression Line, Figs. 19 and 20.—The curvature of the compression line changes as the piston nears the end of the stroke, sometimes even forming a hook. This indicates the escape of steam from the compression space, either through the exhaust or past the piston.

Condensation and Re-evaporation in Cylinder, Fig. 21.—If the expansion

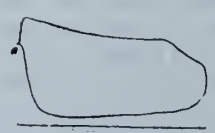

FIG. 20.

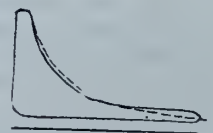

FIG. 21.

curve falls below the theoretical adiabatic line at the beginning of the stroke, crosses and then goes above, it is a fair sign that excessive condensation occurs at the beginning of the stroke, and re-evaporation during the latter part. Superheated steam will remedy such trouble and restore the expansion line to the normal position.

Very Bad Diagrams, Fig. 22.—There is here shown the worst imaginable distribution and waste of steam. The admission is late, there is almost no cut-off, and the steam port is opened so gradually that full steam pressure is not attained until the end of the stroke. The exhaust opens slowly and atmospheric pressure is not attained until two-thirds of the back stroke has been completed. Fig. 23 shows a similar exhaust line, due in the particular case to excessive back pressure from the feed water heater.

Indicating Compound Engines

Indicator diagrams of compound engines are taken in the same manner as on simple engines. Three cards are shown, Fig. 24, taken from a triple expansion cross-compound Corliss engine. The cards for the different cylinders are taken with different scale springs in or-

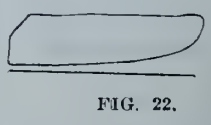

FIG. 22.

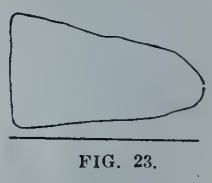

FIG. 23.

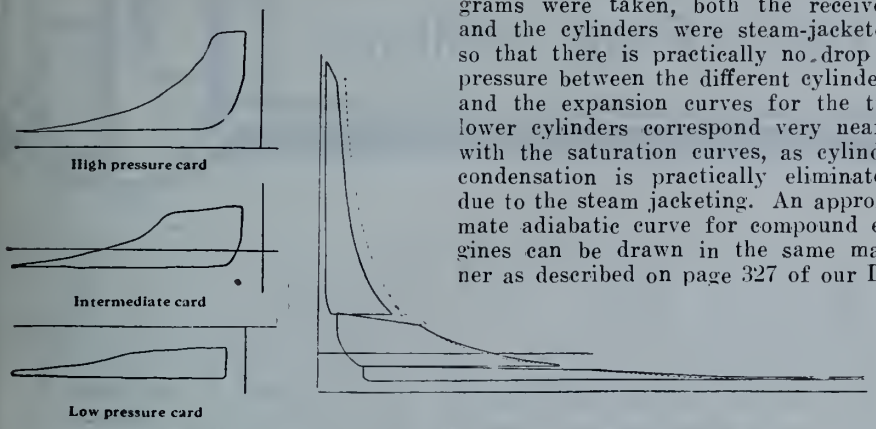
der that their areas may be large enough to show up well. From these cards it is seen that the high pressure cylinder is working entirely above atmospheric pressure. In the intermediate cylinder the pressures run both above and below while the low pressure cylinder works entirely below atmospheric pressure.

In order that these cards may appear in a proper relation, one to the other, they are usually combined on one large diagram. To do this, the pressures and volumes in the several cylinders have to be reduced to a common scale, and when so laid out the different cards fall in their relative positions, as seen in Fig. 25. In the combined card, the total length of each individually represents the volume of the corresponding cylinder in cubic feet. The cards shown on the combined diagram for each cylinder represent the average of several cards for both sides of the piston. In laying out the cards, the distance from the line of no volume represents the mean clearance volume for each side of the piston for each cylinder.

Combined Cards of Triple Expansion Engine

In order to get some idea of the distribution of the steam in the various cylinders, it is generally customary to draw on the combined card, saturation and adiabatic curves. One saturation curve cannot be drawn for three cylinders as the weight of the steam expanding in each is different, due to the different clearance volumes. The saturation curves are constructed by taking the values of the pressure and volume from Steam Tables of the weight of steam expanding in each cylinder. The weight of the steam in each case is the steam used by the engine per stroke, plus the weight of the steam entrapped in the clearance space. The steam used per stroke can only be accurately determined by tests. The weight of steam in the clearance is obtained by knowing the clearance volume in cubic feet and the pressure at the end of compression taken from the indicator card, from which the weight can be obtained from Steam Tables by finding the weight of a cubic foot at the given pressure; from this, in turn, the weight in the clearance volume is easily calculated. This should be done for each cylinder, and saturation curves drawn as indicated.



FIGS. 24 AND 25. INDIVIDUAL CYLINDER AND COMBINED DIAGRAMS OF TRIPLE EXPANSION ENGINE.

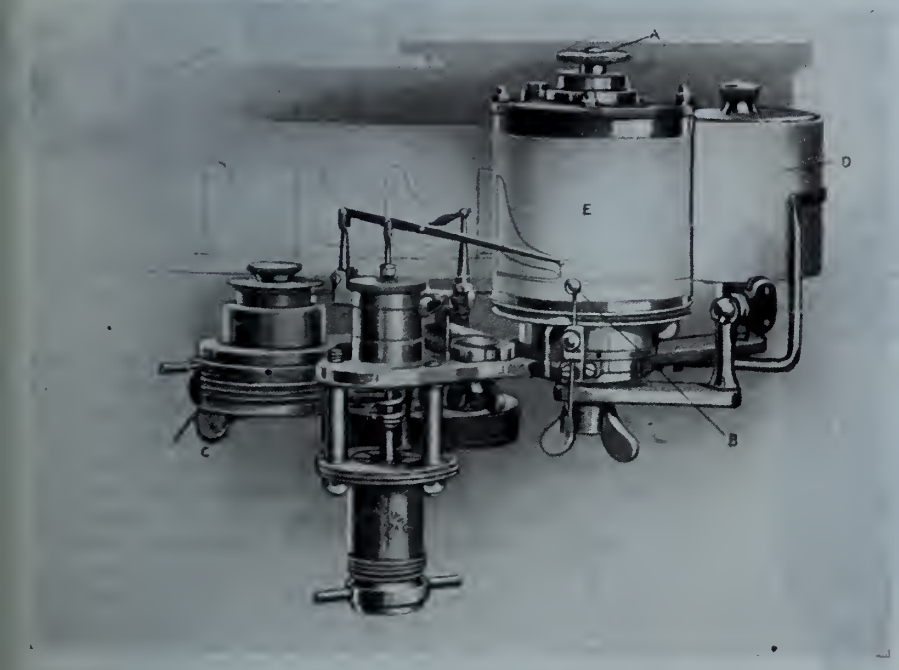
In the engine from which these diagrams were taken, both the receivers and the cylinders were steam-jacketed, so that there is practically no drop in pressure between the different cylinders, and the expansion curves for the two lower cylinders correspond very nearly with the saturation curves, as cylinder condensation is practically eliminated, due to the steam jacketing. An approximate adiabatic curve for compound engines can be drawn in the same manner as described on page 327 of our December issue. This will come slightly above the saturation curve.

By taking indicator cards from compound engines, following points can be determined. First, it can be ascertained if the lead is evenly distributed between different cylinders. Second, the adjustment of the valves can be effected the same as in a simple engine. Third, by the difference in pressure between the exhaust of one cylinder and the admission of the next one, it can be known if the receivers and piping are of proper proportions. An excessive drop between cylinders may indicate excessive condensation or that the piping is too small.

Compounding Advantages

One of the advantages incident to componuding steam engines is the equalization of the turning effort on the shaft. Thus, in a triple expansion engine having three cylinders, the three cranks are usually set at 120 degs. apart, and if an absolutely uniform turning moment is desired, it is necessary that the thrust given on each of these pins be equal. Most steam engines are so designed that this effect will be secured; however, frequently due to the valves not being properly set, it is found that one cylinder is doing much more work than the others and that the benefits due to using more than one cylinder are lost. Therefore one of the points to be ascertained in indicating compound engines is if the net work done in the different cylinders is equal. This can be approximated by theoretical methods if the initial pressure and dimensions of the cylinder are known, but it is much better to find it practically by means of an indicator. If the indicated horse-power from the separate cylinders of a compound engine are not equal, the valves should be adjusted until this is secured.

Equal work in the different cylinders is especially necessary when compound engines are direct connected to alternators which run in parallel. Here differences in angular velocity due to unbalanced work in the different cylinders will cause momentary changes in the voltage of the different generators and cause hunting. This spoils the regulation of the machines and cuts down their capacity.



"TRILL" TYPE CONTINUOUS INDICATOR WHICH GIVES AN INDICATOR CARD PER ENGINE STROKE.

CANADIAN OIL PROSPECTS.

OIL possibilities in Canada are discussed in a statement just issued by the St. John, N.B., Board of Trade, which says:—

"New Brunswick possesses a valuable asset in its oil shales deposits. One of the best English authorities on oil, Sir Boverton Redwood, who made an exhaustive survey of this deposit two years ago, reported that the New Brunswick shale was capable of producing thirty-three Imperial gallons of crude oil per ton of shale, and sixty pounds of sulphate of ammonia. It is estimated that a plant with a capacity of 1,500 long tons per day can retort 547,500 tons per annum, equaling 18,000,000 Imperial gallons of crude oil and 13,687 tons of sulphate of ammonia. The oil may be divided as follows: Gasoline, 2,137,500 gallons; illuminating oil, 7.951.500 gallons; lubricating oil, 2,565,000 gallons, fuel oil, 1.710.000 gallons; paraffine wax, 6,120,000 pounds; coke, 1,530 tons.

This distillation estimate is based upon the old method. By some of the newer methods it is claimed that the New Brunswick shale oil will produce more than three times the above quantity of gasoline per ton. It is believed that there is already sufficient shale available to operate for fifty years at least five plants of the capacity of the one above proposed. The New Brunswick shale is said to be of much better quality than the shale of Colorado, and the quantity is greater. The geological authorities at Washington, recognizing this fact, have been devoting considerable attention to the New Brunswick deposit. Increased development in connection with these deposits is looked for within the next few months."

Steam Power Plant Auxiliaries

STEAM TRAPS—VI.

TWO designs of steam traps are built and marketed by Sheldon's, Ltd., Galt, Ont., these being intended to meet the varied requirements of all classes of steam users. The traps referred to are known as Intermittent Flow, and Universal.

The intermittent flow traps are illustrated in Fig. 34, which shows the interior and exterior of the device. The water enters through the inlet port on the right, the baffle being so shaped as to prevent the water from entering the bucket except by overflowing in the proper way. The loss of buoyancy when filled allows the weight of the bucket to withdraw the valve from the seat, the pressure of steam in the trap causing the water to be discharged upward through the vertical guide tube. A by-pass valve in the cover allows water and air to pass through freely without the trap acting.

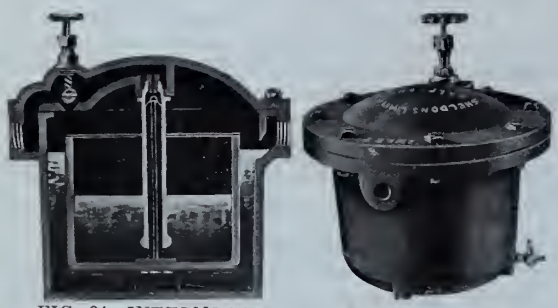


FIG. 34—INTERMITTENT FLOW STEAM TRAP.

These traps are made for either high or low pressure, in five sizes, from ¾ in. to 1½ in., having capacities of 1,800 to 15,000 lineal feet of 1-in. pipe.

The universal steam trap will work on any steam pressure up to 150 lbs. per sq. in., the same trap being applicable to exhaust or low pressure steam as to high pressure work. The sectional view, Fig. 35, shows the principle of construction On first entering the trap, the water fills the open bucket or float, overcoming the weight of the counterpoise and pulling the valve up to a closed position. The continued inflow of the water fills the body of the trap, rising around the outside of the float and gradually increasing its buoyancy until the downward pressure of the counterpoise is sufficient to open the valve. The trap now discharges and lowers the level until reduced buoyancy of the water-filled float causes the valve to close again. When operating under high pressure the water only rises a few inches up the float, but on very low pressure it rises to within an inch of the top of the float before the valve is opened.

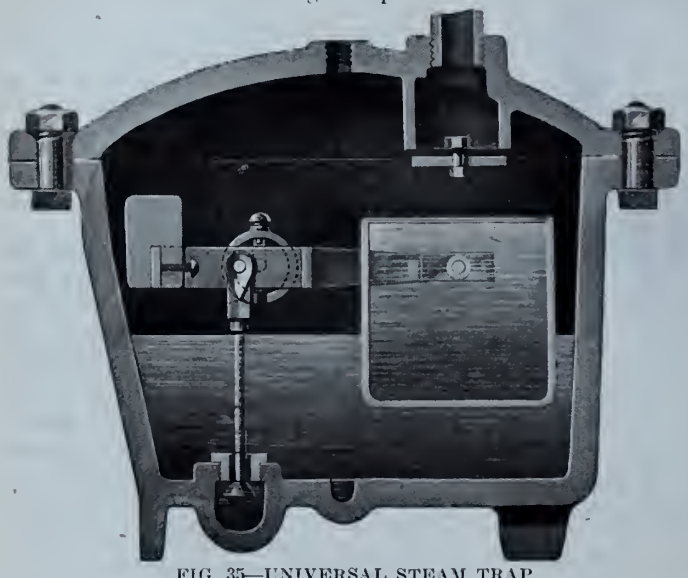

FIG. 35—UNIVERSAL STEAM TRAP.

Pratt Return Steam Trap

This device belongs to that class of apparatus which automatically returns water of condensation into the boiler at the highest attainable temperature. The principal features of construction are shown in Fig. 36, the receiving vessel being of spherical shape, inside of which is a float O suspended from lever P, which in turn is operated from the outside by lever B carrying a counterpoise. Attached to lever B is a rocking arm C, carrying a rolling weight M, which rolls to either end alternately as the feeder fills and is emptied of water, the action of the roller taking place simultaneously with the opening and closing of steam valve D. Condensation is received through inlet G and discharged through F, live steam from H being admitted as required by the action of valve D. This apparatus is manufactured by the Pratt & Cady Co., Hartford, Conn.

Cranetilt Direct Return Trap

This is one of a series of tilting traps built by the Crane Co., Chicago, which includes also non-return traps and three-valve traps, the latter being adapted for service as lifting traps, vacuum traps, and metering traps. This return trap is shown in Fig. 37, and will work on pressure up to 250 lbs. per sq. in. The number of operating parts has been kept at a minimum, there being no interior valves, buckets, levers, or other working parts. The steam and vent valves are on the outside, while the trunnions have the full area of the pipe connections.

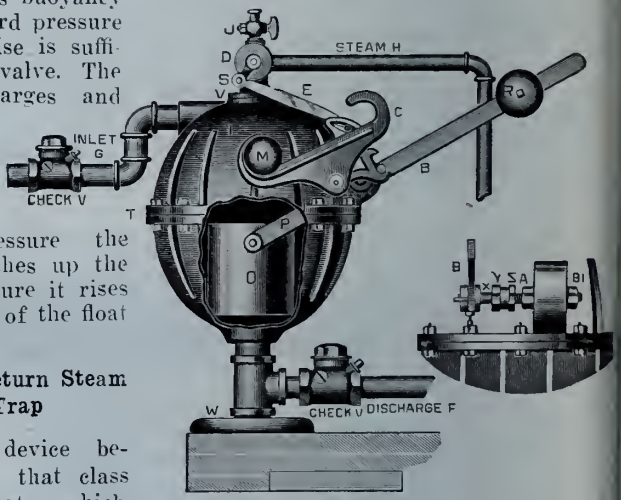

FIG. 36—PRATT & CADY RETURN STEAM TRAP WITH TILTING LEVER.

Condensation enters the trap through the inlet check valve and passes through the divided trunnion tee into the tank. As the tank fills, the weight of water causes it to drop to the bottom of the yoke, and in doing so, the steam valve is opened and the vent valve closed. The pressure now enters through the steam valve and the inner pipe into the space above the water, closing the inlet check

valve and equalizing the pressure in the trap with that in the boiler, so that the water flows into the boiler by gravity from the trap, which should be located not less than four feet above the water-line of the boiler when used for this work.

After sufficient water has left the tank, the counterweight brings it back into the filling position. This action closes the steam valve and opens the vent valve, allowing the pressure in the tank to equal or fall below that in the return lines, after which the operation is repeated.

Morehead Boiler Feed.

This apparatus is illustrated in Fig. 38, the type of trap shown being known as the Morehead Tilting Return Steam Trap and Boiler Feed. This device is constructed with a horizontal tilting steel tank, supported by a vertical pipe and a sloping pipe, which are connected with the trunnion passages. Water enters and leaves the tank by the sloping pipe, the inlet and discharge being through the passage on one side of the trunnion.

FIG. 37. CRANETILT DIRECT RETURN TRAP, SHOWING PATHS OF STEAM AND WATER.

FIG. 38. SECTIONAL VIEW OF MOREHEAD TILTING RETURN TRAP.

while the steam enters the tank through the vertical pipe, the upper end being well above the water-line.

Bolted gland boxes on the trunnions are a feature of the design which avoids trouble, due to stuffing nuts tightening up or loosening with the oscillation of the trunnion bearings. Renewable disc valves are employed, the large valve bonnets being easily removed with an ordinary wrench, and the valve stems fitted with gland packing boxes.

The Canadian Morehead Mfg. Co., Woodstock, Ont., build three additional types of the above apparatus, which meet all conditions arising in steam and gas plants, i.e., condenser traps, non-return or tank traps, and vacuum traps, a feature of the condenser trap being the introduction of a water spray which forms a positive vacuum in the tank, thus removing the condensation rapidly from the system and accelerating the travel of the steam. The vacuum trap operates on systems under a vacuum without breaking the vacuum, and delivers the condensation to any desired point above or below the trap, these various results being obtained through apparatus of similar general construction to the return trap described with such minor variations as are necessary to enable them to perform their duties.

RULES FOR BELTING

IT is difficult and costly to correct a faulty belt drive once it is installed, hence every care should be taken to design it efficiently in the first place. The following formula for belt width has been recommended by C. J. Morrison in an article contributed to the "Engineering Magazine":—

$$\text{Width (ft.)} = \frac{(F \times HP \times 180)}{(S. \times \text{Arc of Contact})}$$

where F = sq. ft. of belt passing over pulleys per minute per horse power transmitted; HP. = horse power; S = belt speed in ft. per minute. The arc of contact is measured on that pulley which has the smaller arc of contact. Experience extending over a period of years and covering thousands of belts shows that suitable values for the factors F and S are 160 sq. ft. and 3,000 ft. per min. for single belts, and 80 sq. ft. and 3,000 ft. per min. for double belts. These factors yield a belt which is somewhat expensive in first cost, but one which is economical in the long run owing to its durability, freedom from breakdown and ability to transmit the required power.

Good single belts are not easy to obtain in widths exceeding 12 inches, but double belts should not be used on pulleys less than 6 in. in diameter, nor triple belts designed on pulleys less than 20 in. in diameter. Belts designed by the above formula and running on cast iron pulleys should have an initial tension of 71 lbs. per inch of width for double belts, 35 lbs. for single, and 106 lbs. for triple belts. Generally it is not easy to measure the tension, in which case it may be provided by deducting 1 in. per 10 ft., as measured over the pulleys using a steel tape. With other than cast iron pulleys, lower belt tension or (preferably) a narrower belt and the same tension may be employed. When using other pulley materials, the belt width as found by the above formula should be multiplied by the following reduction factors:—For leather faced cast iron pulleys, multiply by 0.89; cast iron with projecting corks, multiply by 0.85 to 0.87; wooden pulleys 0.86, ditto with projecting corks 0.88; paper pulleys 0.80, ditto with projecting corks 0.02 to 0.83.

For general machine shop practice, 15 ft. is a good distance between pulley centres, but heavy drives may be on 20 ft. centres; if one pulley is 6 ft. or over in diameter, the pulley faces may be set 25 ft. apart. Open belts should be run with the tight side below; crossed belts with the tight side on top. No belt wider than 8 in. should be crossed if any other method of driving is available. Quarter turn, half turn and other "mongrel" drives are to be avoided. Too much care cannot be bestowed on aligning pulleys accurately, and whenever possible idlers or slide rails should be provided to take up belt slack and permit the use of endless belts. Idlers should always be on the slack side of the belt and as near as possible to the smaller pulley.

Progress in New Equipment

PUMP VALVE RESEATING MACHINES

ONE of the chief factors in the maintenance of high efficiency pump operation is that of the care given the upkeep of the various valves forming part of each pump unit. The effect of wire drawing and the presence of grit in the water soon result in poor fitting valves; it is, therefore, essential that the occuracy of the latter and their seats be maintained. Where the failure of a pump to effectively perform its allotted task means the temporary shutdown of a portion of a plant, the question of prompt repairs is a very important feature.

The accompanying cuts illustrate several applications of the Dexter pump valve reseating machines, and feature their usefulness in the repairing of various types of pumps now in service.

Simplicity of construction of this apparatus is coupled with high efficiency of action; a feature of their operation being the ease with which they are attached to any valve chamber. For the smaller sizes of valves, the single yoke device is used, but for the facing of the larger valves a double yoke is provided. The latter offers additional support for the bearing sleeve, through which the tool spindle operates. This improvement is a highly desirable feature where the valve seats are somewhat below the surface in the valve chamber, as the double clamping facilities offer increased rigidity when the machine is in service. For the smaller sizes, the cutter is driven direct by a handle attached to the spindle, and is operated in a direction parallel to the face of the cutter. In the large sizes, where more power is required, the cutter spindle is revolved by means of beveled gears working in a bracket secured to the upper end of the bearing sleeve; in this case the power handle operates at right angles to the cutter face.

Where the arrangement of the valves does not permit of using the long bearing sleeve, special devices are provided for the facing of the seats, the pressure being obtained by means of adjusting screws operating in the clamp, or against the opposite surface of the valve chamber; the cutter being revolved by means of a ratchet handle, which permits of successful application in the most confined locations. The type of cutters used on these attachments are made of best quality steel, and are otherwise designed to meet their special work. The action

CYLINDER OIL—

Necessary for lubrication, but injurious when that function has been performed

Cylinder oil is necessarily used in engine and pump cylinders, but its usefulness ends with the process of lubrication, and unless it is completely removed from the exhaust steam, serious trouble will develop in condensers or boilers.

To remove oil from exhaust steam, there must be interposed in the path of the steam a series of baffles, which will collect the particles of oil and conduct them away from the current of flow.

Elliott Oil Separators

both collect the particles of oil and conduct them out of the path of the steam.

The baffles of the Elliott Oil Separators, Type "P," consist of a double row of V-shaped plates. The first row merely directs the steam at the proper angle against the second row of baffles, which in turn throws the particles of oil back into the recess angles of the first row, so that the oil is completely out of the path of the steam.

The baffle plates are kept moistened with jets of water from a spray pipe (see spray pipe connection at side of accompanying cut). With the baffle plates in a moist condition, the particles of oil readily form into globules or large drops, and run down into the reservoir.

If a water spray is not used in an oil separator, the particles of oil cling to and eventually gum the baffle plate to such an extent that the steam is enabled to pick up the oil from the surface of the baffle plate and carry it on into apparatus farther down the line.

Further, the baffles of Elliott Oil Separators are removable—they can be taken out of the Separator and cleaned with hot water, gasoline or soda. There is no reason for not keeping the baffle plates in as clean a condition as when the Separator is new.

Removable baffle plates is a feature found only in Elliott Oil Separators.

Bulletin "E" contains a complete description of Elliott Oil Separators, and will be sent on request.

Darling Bros., Montreal, manufacture the foregoing products for Canadian distribution.

MECHANICAL OIL PUMP

THE oil pump shown in the accompanying engraving has been specially designed by the makers for lubricating the cylinders of Diesel oil engines, air compressors and stationary and portable steam engines. The mechanism is so arranged that all moving parts are located inside and are either immersed in oil or automatically lubricated, this feature, coupled with the use of suitable materials for the various parts imparting great durability to the apparatus; the body lid and driving wheel are of close-grained cast iron, while hardened tool steel is employed for the wearing parts, such as ratchet wheel, pawls and eccentrics, with bronze for other parts.

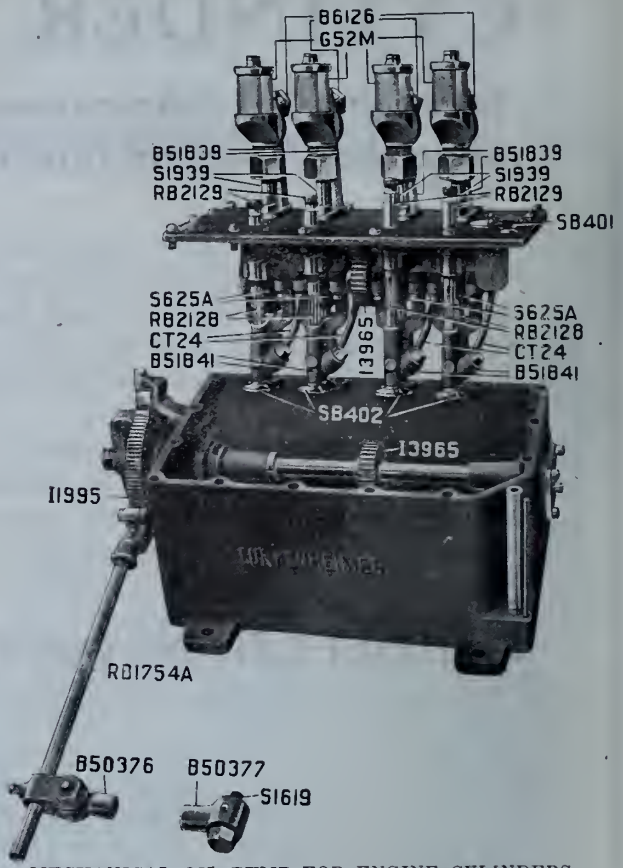
The majority of parts are attached to the lid and are removed with it, facilitating inspection and repairs. The operating ratchet lever is connected to any part operating only when the engine is running. The filling hole is quite large for convenience in filling; a sliding cap to prevent dirt from entering is provided with a removable bronze strainer inside. Each outlet is vided with independent feed regulation and sight feed, the feed being readily adjustable without the use of tools.

The Lunkenheimer Co., Cincinnati, are the makers of this oil pump, which is built with one to four feeds, having capacities from one quart to one gallon.

COMPACT FRICTION CLUTCH

THE friction clutch shown in the accompanying illustration is specially adapted for use as a part of any machine on account of its small size, and when modified to meet the requirements of individual machine tool builders is equally as satisfactory as the standard types. The Johnson clutch, as will be observed from illustration, consists of a body fastened to the shaft, carrying a split ring, in which are inserted a pair of levers. A curve-shaped wedge, which is made a part of the shipper sleeve, forces the levers apart, expanding the ring and bringing its outer surface into frictional contact with the inner surface of the friction cup, the hub of which is made to suit requirements.

The leverage is so compounded that



MECHANICAL OIL PUMP FOR ENGINE CYLINDERS.

very slight pressure is sufficient to operate the clutch. One screw which moves two taper blocks set into the levers adjusts the contact of the ring and cup to any required degree, the screw being easily reached with a screwdriver through a hole in the friction cup. The smooth shipper sleeve entirely covers the working parts, protecting them from dirt, etc.

These clutches are manufactured by the Carlyle Johnson

SINGLE FRICTION CLUTCH WITH PULLEY.

Machine Co., Manchester, Conn., and have been extensively adopted on various types of automatic machines, besides being well suited for line and countershaft service. A double clutch is also made which occupies very little more space than the single type illustrated,

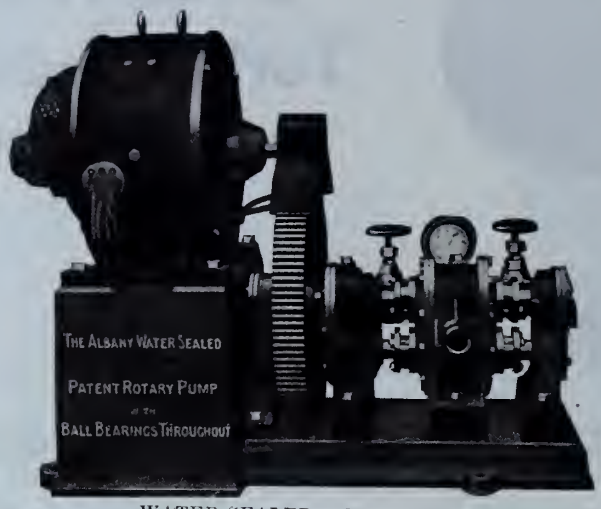
WATER SEALED ROTARY PUMP

THE Albany Pump Co., Toronto, are now building the Albany patent water-sealed rotary pump, which heretofore has been imported from London, England. The general design of this pump is similar to other rotary pumps on the market, in that it consists of a metal casing, inside of which revolve the impellers or wheels. The most important feature of this pump is the fact that slips and leakage have been reduced to a minimum by the introduction of grooves cut along the faces and edges of the teeth, so that in rotating a body of water lodges in the grooves forming an absolutely sealed water-tight joint or cushion between the casing and the rotating rollers, thereby producing an efficient vacuum. Centrifugal force also adds greatly to the efficiency of the pump.



WATER-SEALED ROTARY PUMP.

The pump is suitable for dealing with all kinds of liquids, the wheels and casings being made of different metals according to work for which it is required. Quite recently a pump was installed in Toronto for handling asphalt, which shows the wide range of application of such a unit.

The pump is designed for motor drive through a gear wheel and raw hide pinion, also for belt drive or by gasoline engine. In the latter case, the pump drive is through a roller chain, and not direct connected as formerly. The speed of the pump is the same for the medium and larger sizes, being 200 r.p.m., and the various outputs range from 700 to 60,000 gallons per hour. The speed of the smaller sizes, however, varies, the minimum capacity of the small pumps being 60 gallons per hour.

The "Albany" pump has achieved considerable success in pumping fuel oil, and several outfits have been placed in H. M. Dockyards, and are being largely used by the British and French Admiralties. After an exhaustive test, several of these pumps have been installed in H.M. submarines for pumping water from the trimming tanks.

BRITAIN'S MUNITIONS OUTPUT

THE remarkable increase in Great Britain's output of munitions is dealt with in an official statement just issued, which says:

"From time to time indications have been given of the enormous growth in the production of munitions in this country during the past 18 months. The supply of both guns and projectiles is increasing, as will be seen by the following figures, in which, from its importance in modern methods of warfare, artillery ammunition deserves first place. Taking as a basis for calculation, the average weekly production from the beginning of the war up to the end of June, 1915, the figures show the following rate of progress:

	(a)	(b)	(c)	(d)
18-pdr.	1	6½	17½	43
Field Howitzers (4.5 in.)	1	8	27	
Medium guns and howitzers	1	7½	34½	66
Heavy Howitzers (above 6 in.)..	1	22	94	323

(a) Weekly average at the end of June, 1915.
(b) Weekly average from July 1, 1915, to June 30, 1916.
(c) Week ending July 1, 1916.
(d) Week ending November 25, 1916.

"The improvement may be illustrated in a different way. We are now manufacturing in 8½ days the number of 75 m. m. shells which we were producing during the first year of the war—August, 1914 to August, 1915. The same quantity of projectiles for field howitzers is being supplied in eight days; that of projectiles for medium guns and howitzers in 5½ days, and that of projectiles for heavy guns and howitzers in a little more than one day. The number of shells completed or filled during the week of November 19-26 this year exceeded by about 30 per cent. the stock of munitions, held in reserve at the outbreak of hostilities.

Manufacture of Guns

"Dealing with guns in the same way, it is found that, representing the number of guns manufactured during the first year of war, the following increase have been secured:

	1st year	2nd year	July 31 to Nov. 29, 1916 (4 months)
18-pdr.	100	240	45
4.5 in.	100	654	104
Medium (60-pdr. and 6 in.).....	100	1,848	1,200
Heavy (over 6 in.)	100	623	363

"The manufacture of 18-pdr. guns has had to be slackened during the last period, the equipment of the British army in light field pieces being approximately complete.

"If the average monthly production of guns of all calibre be considered, a splendid development can be observed on comparing the results of the first year with those of the second period of 1916, as is seen from the following table:

	Monthly average for first year	Production during the five weeks ending Dec. 2, 1916
18-pdr.	100	128
Medium	100	4,100
Heavy	100	1,250

Large Increases Shown

"The improvement in the manufacture of machine guns, rifles, grenades and explosives has been equally satisfactory. If the total number of machine guns delivered to the army during the first year of the war be represented by 100, the total could be represented by 1,250 at the end of the second year and by 2,000 on December 2, 1916. Taking as a base the weekly production of machine guns in November, 1915, and representing it by 100, the corresponding figure for the weekly production in November, 1916, would be 410.

"The increase in the manufacture of explosives has been extremely rapid. For every ton of explosive employed in September, 1914, 350 tons were employed in July, 1915, and from 11,000 to 12,000 tons in July, 1916.

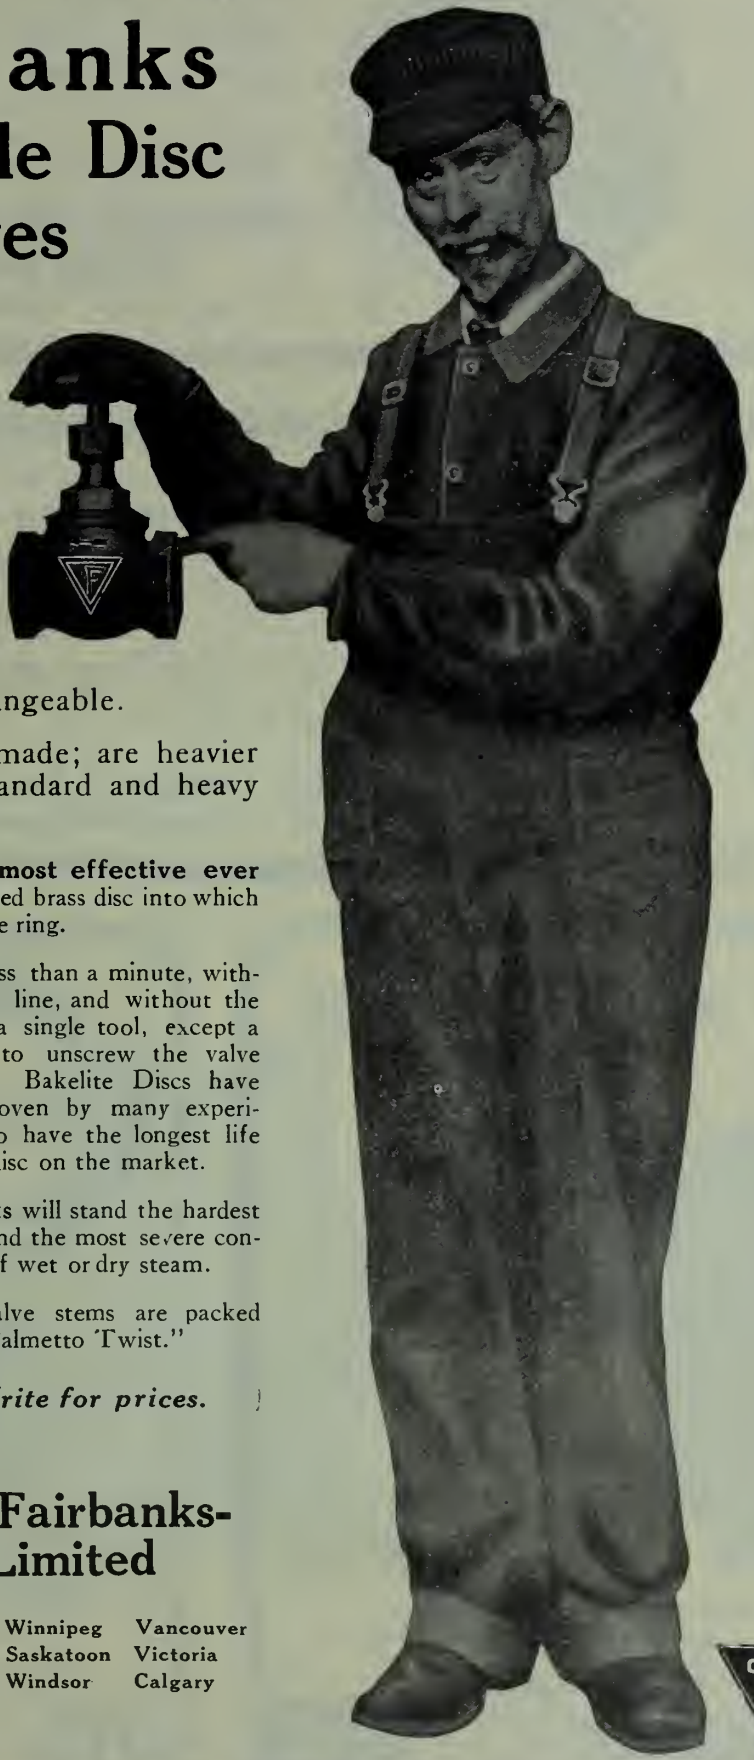
"Between May, 1915, and May, 1916, there was a 38-fold increase in bombs and a 150-fold increase in the weight of the contained explosive."

HIGH STEAM PRESSURES

THE principal advantage of a high steam pressure is the improvement in economy which it makes possible. Steam pressures could be safely increased considerably beyond present practice without any serious difficulties in the prime mover, be it either a steam turbine or a piston engine. The real limiting factor in present-day practice is the temperature. The maximum temperatures commonly employed in steam plants of today, 600 degs. Fah., cannot be exceeded without getting into difficulties with valves, fittings, packings and lubricants. It is interesting to note that a steam pressure of 600 lbs. still makes possible a superheat of 100 degs. Fah. without reaching the limit of 600 degs. total temperature. The entropy diagram readily reveals the amount of extra heat which can be recovered from the expansion of steam of 600 lbs. pressure, and 100 degs. superheat as compared with lower pressures. The total heat necessary to produce a pound of steam of 600 lbs. pressure and 100 degs. superheat is slightly less than that necessary to produce steam under 200 lbs. pressure and 200 degs. superheat. The amount of heat converted into work in adiabatic expansion, however, is 13.5 per cent. higher in the case of the high-pressure steam, both cases figured with the same final temperature and the same condenser pressure, about 28 in. of vacuum.

"Fairbanks Renewable Disc Valves

are strong in construction and service"



Every Engineer who has put them to a fair test will back up this statement.

In design they are very simple, containing few parts and all these interchangeable.

They are conservatively made; are heavier than the corresponding standard and heavy weights.

The Renewable Disc is the most effective ever produced. It consists of a recessed brass disc into which is spun a specially prepared Bakelite ring.

These discs can be replaced in less than a minute, without removing the valve from the line, and without the use of a single tool, except a wrench to unscrew the valve bonnet. Bakelite Discs have been proven by many experiments to have the longest life of any disc on the market.

Fairbanks will stand the hardest usage, and the most severe conditions of wet or dry steam.

The valve stems are packed with "Palmetto Twist."

MARTELL PACKINGS MEAN MORE POWER

Up-to-the-minute Packing Service

Martell packings are not made like the ordinary kind.
They are cut at a tangent to the piston rod and joints on diametrically opposed sides of the piston are parallel. This arrangement of the joints of the ring allows the parts to adjust themselves to every slight inequality of wear in the diameter of the rod as they float freely. Friction and wear upon the rod are practically negligible.
No clearance for wear adjustments need be left between the ends, and sudden failure with this type of packing is impossible.
Use them once and you'll want them always.
Try them and see.

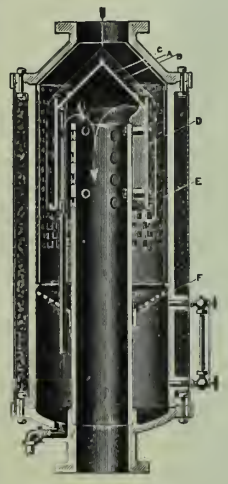
III IMPORTANT THINGS

TO CONSIDER ABOUT A SEPARATOR.



I. **THE PLAN**—Is it sensible, will it work, no matter how large the Separator or how well made?

II. **THE SIZE**—Is it big enough regardless of plan, will it hold a good dose of water?

III. **THE CONSTRUCTION**—Is it strong enough, are flanges heavy, how will it look by the side of a nicely finished engine? Send for catalog and note these points in

BELTING

Driving Gas Compressor at Hotel Planters, Chicago, Ill.

Driving pulley 11½ inch diameter, 610 R.P.M. Driven pulley 79 inch diameter, 8 inch Lenix Idler, 8 ft. between pulley centers. 85 H.P.

Chief Engineer Klein says:—

"The Spartan Belt that you furnished for our twenty-five ton gas compressor is as good as new. We have run same about eighteen months, about sixteen hours per day.

"The belts we used before we had yours put on run us about eight months. Yours is good for a number of years more."

It's the pliability of Spartan Belting and its power of resistance to unusual operating conditions that make it the compressor belt of unequalled success. These same qualities assure you the utmost service from Spartan Belting—whether used on compressors or exposed to the steam, water and acid fumes of the bleachery, or to the extreme heat of the mercerizing room.

In short, Spartan is the belt for all difficult drives. Evidence of this is found in the new Spartan Book. It's a small book, but it shows Spartan Belting operating under a great variety of conditions. You will be interested to receive a copy, and it's yours for the asking.

PRATT & CADY

VALVES

In New Montreal Filtration Plant

Illustration shows part of Control Gallery. In this room there are **16 Hydraulic Operated Pratt & Cady Valves.** These control the passage of air to the pipes below the sand bed for agitating the sand when cleaning, and are only a portion of an order for 128 valves built especially for this plant.

Pratt & Cady Valves were chosen because they have the reputation for absolute reliability under the most trying conditions.

These valves are easily operated, will take the pressure from either side and will not wedge. The stem and stem nut are of solid bronze, preventing rust or corrosion. A trial of these valves will give convincing proof of their superiority, especially in heavy service.

Pratt & Cady Valves are made in all styles and sizes for all purposes.

WE WILL GLADLY SEND YOU FULL INFORMATION ON REQUEST AND QUOTE PRICES ON RECEIPT OF YOUR SPECIFICATIONS.

Manufactured by PRATT & CADY Co., Inc., Hartford, Conn.

Selling the Buyer

(No. 3 of a Series of Short Articles)

Educating Future Customers

NO manufacturer is in business to-day with the avowed purpose of retiring to-morrow. Rather do the majority wish to leave behind them, in their businesses, proud monuments to their earlier efforts and to their integrity and ability.

The importance of educating the coming superintendents and engineers will not be disputed by the far-seeing. It is perhaps a too seldom recognized truth in connection with advertising in reputable technical journals like THE POWER HOUSE, that future buyers can be educated while present sales are being influenced. We would like that thought to STICK.

As one leading manufacturer said to us not long ago in arranging for the use of increased space, "I have been thinking about our advertising a very great deal lately and I have reached this conclusion; that it would be nothing short of absolute folly for us to discontinue our advertising even temporarily. New men are coming into the field, new companies are being formed, new plants being erected. The firemen of to-day will soon be engineers. The superintendents of old plants will secure the same or higher positions in new plants. Changes are constantly taking place. I am signing cheques for firms from whom we ourselves are buying and who were not in existence when I did the buying, personally, a few years ago. If we wish to continue to be as well known as we are to-day, I am convinced we must continue to educate the future buyers through uninterrupted advertising."

Projects and Developments

TRADE GOSSIP

Brantford, Ont. — The City Council contemplate installing a mechanical filltration plant.

Toronto, Ont.—The Gutta Percha & Rubber Co. will build an extension to their power house.

Pembroke, Ont.—The Pembroke Electric Light Co. propose building a hydro-electric power plant.

Aylmer, Ont. — The Town Council contemplate purchasing additional power equipment. Gas engines may be installed.

Amherst, N.S.—The Town Council contemplate the purchase of a motor-driven centrifugal pump in connection with the waterworks system.

Niagara Falls, Ont.—The Pure Ice & Cold Storage Co., has let contract for erection of a 10-ton ice making plant to be ready for operation by March 1, 1917.

Lindsay, Ont.— Plans for rebuilding the cold storage plant of Flavelles, Ltd., are being prepared by the Madison Cooper Co., New York City. It will cost $75,000.

Winnipeg, Man.—The Ontario & Manitoba Cold Storage Co., it is reported, will build a cold storage warehouse to cost about $100,000 in the near future.

Markham, Ont.—By a vote of 96 to 8 the ratepayers on Jan. 1, endorsed the proposition to expend the sum of $6,000 on the extension of the present waterworks system.

Toronto, Ont. — The Township of Etobicoke propose to construct a waterworks system at an approximate cost of $75,000. E. A. James, of Toronto, is the consulting engineer.

East Bella Bella, B.C.—The Gosse-Millerd Packing Co., has had installed a 7-ton ammonia compressor which was furnished by the Armstrong Machinery Co., Spokane, Wash.

The S. K. F. Ball Bearing Co., Hartford, Conn., are reorganizing their Canadian branch the S. K. F. Ball Bearing Co., and have opened offices at 47 King Street West, Toronto.

The Frick Ice and Refrigeration Co., Montreal, have been awarded a contract by Canadian Explosives, Ltd., Montreal, for an 8-ton refrigerating machine, to be installed at Nobel, Ont.

Cayuga, Ont.—It is proposed to install a steel water tank, gas engine and pump, etc., in connection with the waterworks system. Jackson & Lee, Brantford are the engineers.

The Frick Ice and Refrigeration Co., Montreal, have sold a 15-ton refrigerating machine to Curtis & Harvey, Ltd., Rigaud, Que., and a 10-ton machine to the Elmhurst Dairy, Montreal.

Port Colborne, Ont.—Contract for turbines and generators required for the new plant being erected by the International Nickel Co., has been awarded to the Ridgeway Engine & Dynamo Co., New York.

Toronto, Ont.—The Board of Control recommends that the Works Department be authorized to purchase the following suplies during 1917 in the open market: Iron and steel, pig lead, paving pitch, pipe and boiler tubes, rubber valves, etc.

Philip J. Duff, who for over two years has been resident engineer for the John verMehr Eng. Co., on the construction of the new filtration plant, Toronto, has resigned his position to accept an appointment on the inspection staff of the Imperial Munitions Board, Ottawa.

St. Lambert, Que.—Tenders will be received up to January 22, for the supply of a horizontal shaft centrifugal pump, electric motor and switchboard. Specifications may be obtained from H. A. Gibeau, Town Engineer, Town Hall, St. Lambert, Chambly Co., P.Q.

The Duncan Electric Co. has been incorporated at Ottawa with a capital of $150,000 to manufacture and deal in electrical apparatus and supplies of all kinds at Montreal. Incorporators are J. H. Meagher, Henry W. Chauvin and James E. Coulin, all of Montreal.

Winnipeg, Man.—Tenders will be called until Feb. 12, 1917, for works required for the completion of the new Parliament Buildings which include the following, Heating and ventilating, electric conduit and wiring. Thos. H. Johnson, Minister of Public Works, Winnipeg.

The Turbine Equipment Co., C.P.R. Building, Toronto, has been awarded a contract by the town of Mimico, Ont. to supply and install three "De Laval" pumps at the sewage disposal plant. Two pumps will be direct connected to Canadian Westinghouse motors and the third unit to a 40-h.p. gasoline engine.

The Spencer Heating Co., of Canada, Ltd., has been incorporated at Ottawa, with a capital of $500,000, to manufacture boilers, heaters and furnaces of all kinds, with head office at Toronto. The incorporators are: Tilman H. O'Neil, Albert T. Hawley, and Hugh Polson, all of Winnipeg.

South Bay Power Co. has been incorporated at Toronto, with a capital of $1,000,000, to operate power plants in the Sudbury and Temiskaming districts of Ontario, with head office at Toronto. Provisional directors are: A. Fasken, G. H. Sedgwick, and Duncan McArthur, all of Toronto.

Sub-Lieut. Andrew Dyas MacLean has been granted a commission in the Royal Naval Volunteer Service, and is at the present time taking a course at Greenwich. He is a son of Major Hugh C. MacLean, of the Hugh C. MacLean Publishing Co., Toronto and Winnipeg. The young officer went to England to join the motor-boat patrol service.

D. M. Medcalf, chief inspector of boilers for the Province of Ontario, has returned from New York and Washinging, D.C., where he attended meetings called for the purpose of discussing the proposed A.S.M.E. code of boiler rules and regulations. The meeting in Washington was called by the Industrial Commission of Ohio, and the New York meeting by the American Society of Mechanical Engineers.

Hugh McCulloch, one of Galt's most prominent residents, died there on January 8, in his sixty-first year. He was president of the Goldie & McCulloch Co., vice-president of the Galt Malleable Iron Co., and of the Galt Art Metal Co., and a director of the Gore Mutual Fire Insurance Co. A native of Galt, he was closely identified with the industrial progress of the city, but never held municipal office. He was educated at Whitby Grammar School and Upper Canada College.

The Turbine Equipment Co., Toronto, have obtained a contract from the Town of Cornwall, Ont., to supply and instal two 10-in. De Laval single-stage pumps, each of which will have a capacity of 3½ million gallons a day against 180 ft. head when operating individually; 7 million gallons a day against 180 ft. head when operating in parallel, and 4½ million gallons a day against 310 ft. head when connected up in series. This installation is somewhat unique, inasmuch as the pumps will be driven by hydraulic turbines, which will be supplied by the Wm. Kennedy Co., of Owen Sound. The speed of these turbines will be 200 r.p.m., and to enable a speed of 1,650 r.p.m. being attained on the pumps a set of De Laval double helical gears will be installed between each turbine and pump. The contract price of the pumps was $10,075, which includes a few valves and some piping. The price of the hydraulic turbines was $5,000 each.

CATALOGUES

The Cling-Surface Co., 1057 Niagara Street, Buffalo, N.Y., have issued a very unique calendar of special interest to engineers and will gladly send a copy of anyone who applies to them.

Mechanical Stoker.—Bulletin B-2 deals with the type "E" underfeed stoker made by the Combustion Engineering Corporation, New York. The bulletin contains a full description of this stoker, particular attention being given to the principal features embodied in its design and operation. The illustrations show sectional views of the stoker and installations under various types of boilers.

A Chain of Evidence is the title of publication No. 15, issued by the Morse Chain Co., Ithaca, N.Y. This bulletin, although bearing a sub-title, "Small Power Drives," is not confined to small drives, but includes drives up to 100 h.p. The bulletin deals with the characteristics, design and efficiency of the "Morse" silent chain drives and contains a number of illustrations covering a variety of installations which feature the wide field of application. A data sheet is included for use in the design of "Morse" silent chain drives.

Crossley Oil Engines.—A bulletin dealing with the new Crossley oil engine for running on crude, residual and refined oils, has been issued by Crossley Bros., Ltd., Openshaw, Manchester, England. The bulletin contains full details covering the design of this engine and its attachments, while the advantages claimed for it are given in detail. Reference is made to the economical fuel consumption of the engine, and its adaptability for burning various qualities of crude and residual oils. Details of a test on a 95 b.h.p. engine are included. The bulletin is fully illustrated.

Ammonia Fittings and Supplies.—The Canadian Ice Machine Co., Toronto, are distributing a new high class catalogue, dealing with the "York" ammonia fittings and supplies. This catalogue, which supersedes all pervious issues, illustrates and describes standard types of fittings, etc., for which patterns are already made. A complete line of fittings and supplies is dealt with as used in refrigeration plants, the first part being devoted to fittings and the second covering various types of condensers, ammonia receivers, coolers, distillers, oil and steam separators, brine coolers, and filters, etc. An extensive line of valves and fittings are illustrated, accompanied by tables giving the principal dimensions for each size. The concluding pages contain views of numerous installations featuring various types of "York" refrigerating machines. The catalogue contains 132 pages, with exceptionally good half tones. Copies may be had on application by interested readers.

BOOK REVIEWS

Graphical Solutions of Electric Railway Problems.—In an effort to overcome the difficulties attendant upon the use of analytical methods in the solution of electric railway problems involving the characteristics of motive power, A. M Buck, of the Engineering Station, University of Illinois, has developed a series of graphical methods which supply an accurate and easy means of attack applicable to any possible combination of electric motor characteristics and any range of conditions which may be met in practice. Diagrams have been developed to set forth the relationship between motor current and speed, between current and tractive effort, between speed and tractive effort, between speed and time, etc. The results of Professor Buck's studies are set forth in Bulletin No. 90 of the Engineering Experiment Station. Copies may be obtained on request from W. F. M. Goss, Director, Urbana, Illinois.

Do You Know Why The Steam Trap SARCO

Is used by nearly all the big industrial concerns?

THIS IS WHY

The Steam Trap SARCO is operated by the expansion of a liquid operating a spirally corrugated tube. There is no other steam trap made which uses liquid expansion and none can use this enormously powerful and reliable operating medium without using also the Sarco tube. Therefore of all thermostatic traps the SARCO claims to be the most positive—and it can be supplied not only for vacuum heating systems but for low pressure and high pressure steam up to 200 lbs. Do you know any other thermostatic trap used successfully for pressures above 50 lbs. or even as high.

Then as to installation. The SARCO fits in anywhere. (1" size measures only 7½"); it needs no floor space or building up, but can be used as an elbow or bend, in the discharge. Although it does just the same work, it is not a heavy, cumbersome affair like a float or bucket trap. It is not a tank, but a piece of live pipe. It cannot freeze and will not permit freezing of the pipe line unless steam is in the line the trap is wide open to discharge.

Price—it is the cheapest trap on the market in first cost—cost of installation and cost of upkeep.

Take a trap on thirty days' trial and prove this for yourself.

NOTICE

TO

Stationary and Hoisting Engineers

Everyone operating a STATIONARY steam plant of 50 h.p. or over in the Province of Ontario must hold a Stationary Engineer's Certificate from the Board of Stationary and Hoisting Engineers. Anyone operating such a plant without a Certificate is liable to the penalties set forth in the Stationary and Hoisting Engineers' Act.

Everyone operating a HOISTING steam plant working at a pressure of 20 pounds or over, irrespective of horse power, and used for hoisting in structural operations or excavating purposes, in the Province of Ontario, must hold a Hoisting Engineer's Certificate from the Board of Stationary and Hoisting Engineers. Anyone operating such a plant without a Certificate is liable to the penalties set forth in the Stationary and Hoisting Engineers' Act.

Application forms for obtaining STATIONARY or HOISTING Engineers' Certificates, may be had upon applying to the Chairman.

HON. F. G. MACDIARMID, Minister of Public Works and Highways.

W. C. McGHIE, Chairman of Board.

McDANIEL IMPROVED STEAM TRAP

FOR HIGH OR LOW PRESSURE.

Steam can't blow through. They have large discharge valves and cannot be flooded from sudden flushes of water.

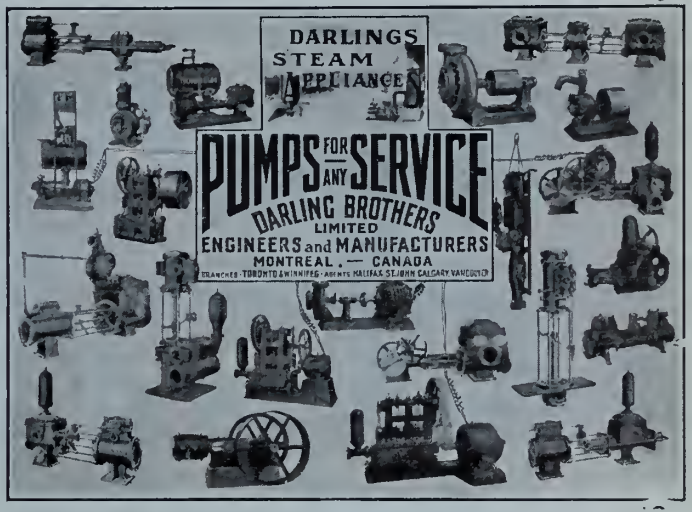
THIS DIRECTORY IS FOR YOUR USE

IF you want the correct 'phone number, you use the official telephone directory. If you wish to definitely ascertain the location of a certain street, you consult a city directory.

If you are in need of equipment of any description, the best way to buy it is to consult our Buyers' Directory. If what you require isn't advertised in this particular issue, write to the firm or firms listed under the title of the machine you require, and catalog or literature will be gladly sent.

The firms listed in this Directory think enough of your business to ask for it, and they have unlimited confidence in the product they advertise.

Consult this Directory and you can't go wrong.



Self-Lubricating

In Cans
6, 12, 25 and 50 lbs.

SAFETY PLASTIC
METALLIC PACKING
FOR STEAM, WATER, AIR, GAS, ETC.

LASTS FOR YEARS AND NEVER WEARS THE PISTON ROD.

Guaranteed to stand steam temperature up to 550 degrees Fahr.
Guaranteed to stand hydraulic pressure to 5,000 pounds per square inch.
Packing furnished in bulk and in thin Cotton Tubes, sizes 3-16 to 1½ inch, 36 inches long, or in special lengths to fit your stuffing boxes.
Empty Cotton Tubing in assorted sizes FREE OF CHARGE with orders for the packing in bulk form
The tubes are easily filled and they save you the expense of carrying a large stock of packings in different sizes.

Send for FREE SAMPLE and particulars.

MANUFACTURED ONLY BY **STEEL MILL PACKING CO., WINDSOR, ONT.**

Practically Frictionless

Any Quantity sent on APPROVAL

BABCOCK & WILCOX LIMITED

LAGONDA
BOILER TUBE CLEANERS

The latest Lagonda Water and Air-Driven Boiler Tube Cleaners are the most powerful and efficient tube cleaners made. They develop higher speed and greater power than has heretofore been secured with any Turbine Cleaner, and their use will materially shorten the time required in cleaning boilers.

These new Lagonda Cleaners are built for all sizes of tubes, either straight or curved, and they can be driven by water, air or steam.

Ask for Catalog L.

LAGONDA Multiple Water Strainers

The Lagonda Multiple Water Strainer in your water supply main will remove all objectionable solid matter and insure constant and economic conditions of pump and condenser operation. They are easily and quickly cleaned, without interruption of water supply, and take up small floor space. **Ask for Catalog R-2.**

UEHLING WASTE METER

COMBINED

CO_2 AND TEMPERATURE RECORDER

Record of CO_2 and stack temperature on one chart.

CO_2 Indicator for Boiler Front

Does your fireman know how much fuel he is wasting? Do you know?

The **Uehling CO_2 Recorder** makes a complete 24 hr. record of your combustion efficiency and the **CO_2 indicator at the Boiler Front** holds the fireman responsible.

Get more **Steam** per pound of **Coal** and reduce your annual fuel consumption.

Let us know the number and size of your boilers and coal consumed per year, upon receipt of which information we will be glad to send you full particulars.

Let us hear from you. We are pioneers in the manufacture of Indicators and Recorders for Power Plant purposes.

Send for our Bulletin No. 110.

2008 Empire Building **New York City**

TRADE MARK

Starrett

REG. U.S. PAT. OFF.

Hack-Saws

IN the engine room there are numerous jobs requiring a hack saw which will cut all kinds of metal smoothly and evenly.

No matter whether you wish to cut tool steel, wrought or cast iron, or electrical conduit, you'll find that Starrett Hack Saw Blades No. 103 will cut faster and last longer than any other saws.

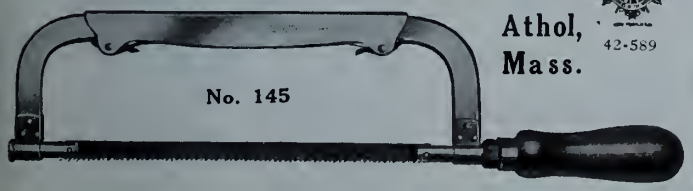
Write for our catalog No. 21CD, which contains useful information about hack saws and tools, many of which should be in every engineer's kit.

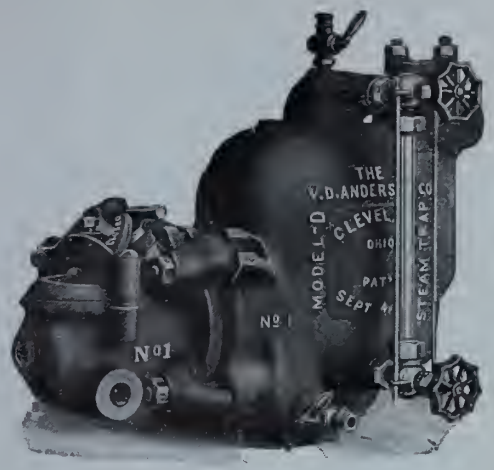
The L. S. Starrett Co.

The World's Greatest Toolmakers.

Athol, Mass.

42-589





It Isn't Magical

Although the results would lead you to believe it was. By a simple adjustment it can be adapted to a 60-lb. coil in the vacuum pans or a 160-lb. main to protect the engine.

Model "D" Steam Trap

delivers live, hot, dry steam to the required parts and keeps it dry. It is impossible for any condensation to gather. Three inches of water seals the valve and seat, so when condensation is exhausted no steam is allowed to escape.

Anderson Model "D" Steam Trap can be used on any steam apparatus at pressures varying from 250 lbs. to gravity, and also where there is condensation in air lines.

If you are troubled with condensation, get in touch with us. We are ready to co-operate.

The V. D. Anderson COMPANY

1935 West 96th St., Cleveland, Ohio

Don't buy that New Electrical Apparatus Just Yet

WE can supply you with high-grade apparatus that has been slightly used and discarded through no fault of its own, at an **immense saving in cost.** For instance, in many cases we take over entire plants simply because of changed conditions such as increased capacity, change of system, etc.

EVERYTHING IS OVERHAULED AND REFINISHED BY US AND **GUARANTEED** AS GOOD AS NEW, BOTH ELECTRICALLY AND MECHANICALLY.

Our catalogs of offerings should be in the hands of every power plant superintendent each time they are gotten out, and it will be worth while for anyone interested in this class of power plant equipment to be on our mailing list to receive **all** offerings.

Nearly all of the principal power, lighting and street railway plants in the United States are our customers.

WRITE FOR OUR LATEST CATALOG of **Power House Equipment, Street Cars, Motors, Hoists, Compressors, etc.**

MACGOVERN & COMPANY, Inc.

114 Liberty St., New York City

The Wrench of 25% Greater Efficiency

TRIMO PIPE WRENCH

Two new features have been recently added to the Trimo Pipe Wrench, namely Nut-Guards, in all sizes, and unbreakable steel frames, in leading sizes.

The Nut-Guards prevent the accidental rotation of the nut while in use.

These improvements add 25% to the usefulness of the tool.

The Trimo Pipe Wrench is made with wood handles in 4 sizes, 6-in., 8-in., 10-in., 14-in. and in steel handles in all sizes, 6-in. to 48-in. inclusive.

All Trimo Pipe Wrench parts are interchangeable.

The inserted jaw in the handle can he readily replaced when worn, thus adding to the life of the tool.

Nut with Nut-Guards

Inquiries from Importers and Dealers Solicited. Send for Catalogue No. 55.

FOXBORO
TRADE MARK

Simplicity

We illustrate herewith the interior construction of "Foxboro" Improved Recording Gauges and Thermometers.

No other type of instrument offers such simplicity and at the same time so many marked improvements. Here are a few of them, all sound arguments in favor of "Foxboro" Recorders.

Supported Helical Tube actuating movement;
No Multiplying Levers! Absolutely Dead Beat.
Automatic Self-Centering Chart Holder.
Automatic Release Pen Lifter.
Micrometer Adjustment on Pen Arm.
Special Design Clock three-point support, adjustable through dust-tight box.
Non-Corrosive throughout.
All parts interchangeable.
All types supplied in Round Form Case.

Write to-day for Bulletin No BH-96, stating what you are interested in.

MACLEAN'S MAGAZINE *for* February

Just suppose you were made Editor of MACLEAN'S MAGAZINE for one issue!

WHAT would you provide for your readers? You would probably want some good short stories, and you would like to offer chapters of a good serial. You would want something in lighter vein. Perhaps some verse. Certainly some serious articles of an informative and critical nature. Probably you would want everything—contributions and illustrations—to be by Canadians. Good! But who are they? And could you get their work?

Look at what the regular editor, T. B. Costain, has provided for the February issue of MACLEAN'S:

A serial story by **Sir Gilbert Parker**—"Jordan is a Hard Road."

A short story by **H. G. Wells**—"Into the Abyss."

A complete novelette by **A. C. Allenson**—"Danton of the Fleet."

A gripping sketch of "The Greatest Hotelman in the World"—a Canadian, by name John McE. Bowman, of the Hotel Biltmore, New York; and the man behind the Manhattan Hotel, New York, and the hotel now building in the same city, The Commodore, and the new Canadian hotel, The Devonshire, to be built this year in Toronto. **W. A. Craick** gives the story of this remarkably successful and interesting man—a veritable romance of achievement.

Stephen Leacock is in the February MACLEAN'S with one of his inimitable sketches—this one entitled—"In Merry Mexico." What a fancy, what a humor this man has! He roams the earth, and always is visiting some land or country in the spotlight of the world's history.

Then Editor Costain has **Miss Agnes C. Laut** in the February issue with a timely and thought-provoking article, "The Elections and Canada." She is writing of the American elections of last November, and in her virile style and with her amazing inside knowledge of things political, she gives all Canadians much to think about, and a wider vision of the place Canada holds in world affairs—dwelling especially on the new Anglo-Saxon relations which will be the result of the war now being waged, and which gives promise of involving the United States. Miss Laut's contribution is well worth reading.

H. F. Gadsby, free lance, ever a-tilting at politicians and politics, and never failing to get under the guard of parties and partisans, writes sparklingly on "How Premiers Control Their Cabinets" — of piquant interest in view of Sir Sam Hughes's recent encounters with Premier Borden. Gadsby studies other Canadian Cabinets than those of Premier Borden's. Good reading, this.

Then Editor Costain starts in this February issue of MACLEAN'S a new department—snappy biographical sketches and zestful stories of notable and interesting Canadians. You will enjoy this yourself and so will all others to whom you may introduce MACLEAN'S MAGAZINE.

The usual departments—Review of Reviews and "Information for Investors"—are present as usual; and illustrations by these Canadian artists, C. W. Jefferys, Harry C. Edwards, Lou Skuce, E. J. Dinsmore, assist to give the February MacLean's *distinction and appeal.*

Now if you have been keeping in mind yourself—as a possible editor of MACLEAN'S MAGAZINE for a single issue—do you think you could excel or equal what the regular editor has provided for MACLEAN'S readers?

At All News-Agents, Fifteen Cents

Davis Pressure Regulators Save Steam

Screwed or Flanged Standard or Extra Heavy

When the Boiler Pressure is Too High—

and unduly taxes your auxiliaries and a lower pressure would operate them more efficiently and economically, a

Davis Pressure Regulator

is the means of attainment. It will automatically deliver a constant, unvarying pressure at any lower predetermined pressure desired, irrespective of the varying initial pressure. Being simply constructed without diaphragms, springs, toggles, packings, small communicating parts or pilot mechanism, it has long life and is unusually free from defects and troubles incident to other reducing valves.

Davis Reducing Valves are registered in all Provinces of Canada as required. All valves fully guaranteed.

Send for General Catalog.

We Make—

Pressure Regulators
Balances Valve
Float Valve
Steam Trap
Back Pressure Valves
Exhaust Relief Valves
Stop and Check Valves
Pump Governor
Damper Regulator
Radiator Air Valves.

INGLIS BOILERS

THE STANDARD FOR MATERIALS, WORKMANSHIP, VALUE AND SERVICE FOR 52 YEARS.

We make boilers for all kinds of service.

We are also sole Canadian manufacturers of the Erie City Water Tube Boilers. A very large number in use. Every one of our installations is a working testimonial of their efficiency and economy.

Our representatitves will be pleased to show installations of our different types of boilers to prospective customers.

The John Inglis Company Limited

ENGINEERS AND BOILERMAKERS

14 Strachan Avenue Toronto, Canada

J. M. T.

The Perfect

REDUCING VALVE

Will Not Equalize

J. M. T. REDUCING VALVE FLANGED.

J. M. T. REDUCING VALVE.

With lock shield and key adjustment.

J. M. T. REDUCING VALVE.

Iron Body Bronze Mounted

To allow for the unequal expansion of the metals, the bronze body lining is suspended from the centre leaving a space between the lining and the body.

The J. M. T. Pressure-reducing Valve, being controlled by the variation of the reduced pressure, automatically reduces and maintains an even pressure of steam or air regardless of the variation of the initial pressure or the volume of steam or air required.

The valve is provided with a dash pot which prevents chattering or pounding.

The reduced pressure can be varied as desired by turning hand wheel on top of valve, which is provided with locking ring.

J. M. T. reducing valves are made to suit every requirement and are sold with the well-known Morrison guarantee.

J. M. T. REDUCING VALVE.

(Low Pressure.)

For reduced pressures under 5 lbs. per sq. inch. The large diaphragm provides ample power to operate the valve and make the valve very sensitive to the slightest change in the reduced pressure.

Tanks and Bins

WHEN next you want a well-built Steel Tank or Bin of any kind – write us.

We are doing a lot of this work just now and have thereby so reduced our manufacturing costs that we are able to offer you a high-class product in this line at prices that are unusually attractive.

We build, in all sizes:—

PRESSURE TANKS
STORAGE TANKS
SETTLING TANKS
WASHING TANKS
STORAGE BINS

ALSO

STEEL BUCKET ELEVATORS
STEEL BUCKET CONVEYORS
STEEL TROUGHING
RIVETED STEEL PIPE

Send us your sketches for quotation. We specialize in turning out difficult steel plate work—built right, at a reasonable price.

Some of the larger jobs we have recently handled are illustrated in our Booklet No. 400. A post card will bring it to you.

Murphy Automatic Smokeless Furnaces

Between January 1st and October 1st, 1916, we received 11 repeat orders from Canadian users for 17 furnaces—5620 HP.

January 4th, 1917, contract was executed by BRITISH CORDITE, LTD., for ten 400 HP. units—4000 HP. to be installed at Nobel, Ont.

Same time period we received *33 repeat orders from American users of Murphy Furnaces.*

PEILER'S SERVICE—

THE simple matter of buying goods at one price and selling at another never made a successful business. The ***Element of Service*** is what adds permanence to any organization, and the success of such organization is measured only by its ability to serve. The factor of ***SERVICE***—to the customer—always has been, and is, what has guided us in making connections with manufacturers of power plant specialties.

WE have had many years' experience solving difficult power plant questions, of all kinds and conditions, and the benefit of this experience is yours in dealing with us. If your conditions are not suitable for equipment supplied by us, we do not hesitate to advise what we think will overcome your difficulties.

ON this, and the opposite page, a few of our lines are shown. In our opinion, after long experience, with many tests and trials, they are the best, will stand up the longest, and give the most efficient service, of any that are made on the continent.

H. L. Peiler & Co.
311 Kent Building, Toronto, Ont.

Mechanical Regulation of Boiler Feed Water

By the use of the "S-C" method you are assured of a continuous feed at all times load is on boiler. The graduation in rate of feeding is entirely dependent upon the load and fire conditions. The Regulator will carry a constant level on steady load—higher level on light load and lower level on peak loads. Variation in water level is entirely dependent on inclined position of generator which is adjustable while operating under full load.

Bulletin No. 80 explains all.

Generator or Actuating end of Regulator.

Regulating Valve Placed at Any Point, Any Position.

"They were evidently satisfied"

WITH

GALT SPRINKLER STOKERS

A prominent manufacturing concern (name on request), installed 2 of our stokers on January 8th, to burn screenings with *natural draft,* and on January 22nd placed a further order with us to supply *as soon as possible,* stokers for their other boilers.

The smooth, continuous feeding of the fuel to the furnace produces a brilliant and perfectly level fire, combined with smokeless combustion. Galt Sprinkler Stokers operate with your present grate bars and furnace settings, and can be installed in a few hours by any engineer.

It will pay you to investigate this wonderful machine. Ask for catalogue.

How Much Coal Is There In Your Ash Pit?

If you are still using the old, uneconomical type of shaking and dumping grate, you will find that a big percentage of coal is wasted daily—dumped with the ashes.

THE McNAUGHTON (SECTIONAL) ROCKING GRATE

is so constructed that it insures the complete combustion of every pound of coal. Only the ashes can slip through the grate and that is effected by a rocking motion—not by dumping.

*Used in over **1200** power plants.* *Ask for literature.*

Results in service—

prove the efficiency, delivering capacity and durability of the

LUNKENHEIMER Automatic Injector

Users everywhere proclaim the merits of this simple, yet efficient boiler feeder.

It excels all others because **it will deliver more water per pound of steam, is absolutely automatic at all times, and will restart instantly after a temporary interruption of either the steam or water supply.**

Its capacity is diminished in a lesser degree by long lifts and hot feed water, and the amount of water delivered can be graded over fifty per cent.

The correct design of the tubes and large areas through the body account for its excellent performance; the special hard bronze composition used, for its durability. All parts are made to gauge and are renewable.

THE LUNKENHEIMER EJECTOR is an efficient machine for raising water from pits or deep wells, filling or emptying tanks, etc. It embodies the **same excellence in design, high quality material and workmanship** as the injector.

Made in eight sizes, capacities 250 to 11,000 gallons per hour. Other sizes on special order.

Buy the best, viz., "Lunkenheimer"—for efficiency, satisfaction and economy.

Your local dealer can furnish them; if not, write us.

BOILER INSPECTION

The Steam Boiler Act, Chapter 252 R.S.O., 1914, With Amendments Chapter 58—6, George V.

STEAM BOILERS.

All Steam boilers constructed for use in Ontario must be built from designs which have beeu approved and allotted a registration number by the Steam Boiler Branch.

Used boilers, boilers sold or exchanged, and unregistered boilers brought into the Province must be inspected prior to being put into operation.

Notice of repairs to steam boilers, stating the nature and extent of same, must be sent to the Steam Boiler Branch, and should such repairs be considered extensive by the Chief Boiler Inspector, the boilers will require to be inspected.

In each and every case the inspections must be made by Inspectors authorized to inspect boilers under the Steam Boilers Act, who are employed only by the Steam Boiler Branch of the Department of Public Works. Official certificates with the maximum working pressure stated thereon are issued to the owners of the boilers so inspected.

STEAM PIPING.

Drawings and Specifications of all high pressure steam piping must be approved and registered by the Steam Boiler Branch before any work of installation is commenced. The drawings submitted should show clearly the dimensions and layout of the main steam lines. Full particulars should be given as to the material used in the construction of the piping, and all valves and other fittings used in connection therewith must be of approved make.

Any deviation from the above requirements shall be deemed a violation of the Steam Boilers Act.

All communications in this respect should be addressed to the Steam Boiler Branch, Department of Public Works, Parliament Buildings, Toronto.

HON. F. G MACDIARMID, Minister of Public Works and Highways.

W. A. RIDDELL, M.A. Ph.D., Supt. Trades & Labour Branch

D. M. MEDCALF,
Chief Inspector of Steam Boilers.

Morehead
Back to Boiler
SYSTEM

60,000,000 Tons of Coal Thrown Away Yearly

Over 600,000,000 tons of coal are mined yearly in the United States and Canada. Ten per cent. of that enormous production is carelessly, needlessly wasted. Over Sixty Millions of Dollars are spent each year in producing—nothing, and yet, a mere fraction of that great loss, if properly applied, would save those wasted millions for years to come.

You are contributing to this national waste—but you can stop it.

Steam, after its expansive energy is exhausted, is not through with its job. There are heat units left—live, tangible heat units which were purchased by coal at the boiler's mouth.

What Are You Doing With These Heat Units?

This condensation, in other words.

With the Morehead System installed on your steam lines the condensation is automatically returned to the boiler—without pumps—and at any temperature. It is the last link from boiler back to boiler—the unused energy is not wasted.

If you would save this ten per cent. and have a clear steam system which drains automatically, write to-day for particulars.

THE BELT WITH A GRIP

"Lincona"

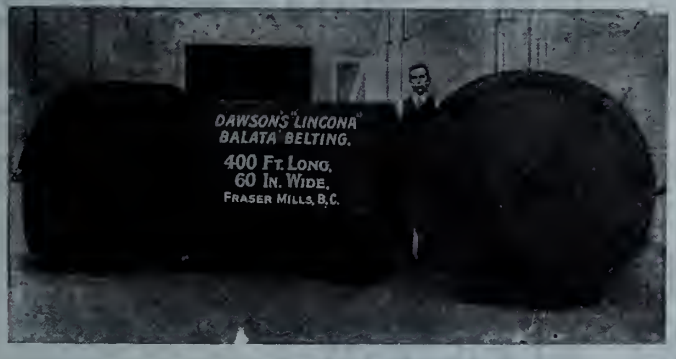
BALATA BELTING

will pick up a load suddenly better than any other type of belting

BECAUSE

it has a GRIP that no other belting has and requires no dressing.

"Lincona" will give you the maximum transmission of power



"Lincona" is the strongest Balata Belt Made.

The tensile strength of "Lincona" is almost double that of leather belting and there is less stretch and straighter running than any other type of belting.

The secret of the greater strength of "Lincona" Balata Belting is in making the Balata a fluid which will saturate the duck, instead of a paste placed on and rolled in. The fluid Balata used in the "LINCONA" process also allows the duck to be compressed more closely, so producing a Belt thinner for the number of plies. This gives a stronger wearing surface to the pulley and less friction.

"Lincona" Balata Belting can be exposed to snow, rain and every condition of weather without injury. It can be run in water without trouble. Write us about your specific needs.

TWENTY-ONE YEARS
ELEVEN YEARS WITHOUT LUBRICATION
AND GOOD FOR MANY YEARS MORE

GEORGE A. DIEMER, NEWBURGH, NEW YORK.

Magnolia Metal Company. July 22, 1916.

Gentlemen:

Referring to my letter of February 21st, 1911, advising you that sixteen years previously I had babbitted with Magnolia Metal a high-speed lathe — 3,500 R.P.M. — and countershaft hangers, and that they were still running in a No. 1 condition, and that a head shaft for motor drive had run much longer and had not received a drop of lubrication for the past six years.

I am pleased to advise you that this lathe and shafting are still running in the same easy way on the same Magnolia bearings, and that the only attention they have received since then, that I can recall, was last October, when I tested an invention to find the H.P. consumed. These bearings are still in fine condition, and will give many more years of good service.

Very truly yours,
GEORGE A. DIEMER.

How *could* there be a better way?

SILENT chain driving affords the combined advantages of belting and gearing without their disadvantages.

In simple terms, a silent chain drive to either machine, line or countershaft is—

(1) Positive in action (the same as is gearing).

(2) Flexible and elastic (the same as is belting).

(3) 98% to 99% efficient throughout its life (a saving of 2% to 20% in power, compared to gearing and belting).

(4) Quiet in action (but without the slip of belting).

(5) Not affected by heat, cold or moisture.

(6) Very reliable (no necessity for frequent tinkering and repairing, as with belting, nor frequent and copious lubrication, as with gearing).

Of the several makes of chains of the "silent type," the MORSE Chain is the one *different* chain—the exclusive "Rocker-Joint" construction setting it clearly apart from all other makes, and, as the service evidence seems to show, well above every other make in actual value (efficiency, durability and economy) to the user.

Each of the three bulletins illustrated opposite tells the complete story of the MORSE Silent "Rocker-Joint" Chain.

You may have one or all of them, without obligation of any kind, simply for the asking. Do it now.

Good things for the POWER PLANT

If You Could Make a Safe Legitimate Investment of $100.00 Bring You Back $200.00 in a Year's Time, Would You Do It?

We would and we think *you* would. However, the mere doubliug, tripling or quadrupling of money doesn't begin to touch the possibilities from Cling-Surface.

As we recently showed you, Cling-Surface treatment of belting cau be the direct means for saving from $90.00 to several thousand dollars per year by reducing transmission friction in belted plants of from 50 to 1,000 h.p. Considering the very small expenditure for a few pounds of Cling-Surface and considering the large return, what better investment could you make?

An example: The 10-inch belt in the plant of the Aird-Don Co., Troy, N.Y., as shown in the picture, transmits 40 b.p. from a 14-foot to a 30-inch pulley on 30-foot centers. The engineer here, Mr. Louis J. Landmeir, tells us that scientific treatment of this belt with Cling-Surface costs him only 90 cents per year. Then he goes on to say:

"Belt has had Cling-Surface treatment about 3 years. Is very pliable. No trouble with lacings pulling out or with belt slipping. Never have to take up belt. Used various belt dressings, but never had such success as with Cling-Surface."

Cau you imagine how 90 cents could have been spent to better advantage?

Don't you think Cling-Surface worth investigating? Are your belts pliable? Do they run slack like the one in this picture? Do they pull maximum loads without slip? Are they waterproof? Durable? Troubleless?

They would be under Cling-Surface treatment.

Proof of all our claims awaits your inquiry.

We quote f.o.b. Toronto.

Mechanical Refrigeration

Saves Money—Increases Profits

By reducing your operating expenses and increasing your output, MECHANICAL REFRIGERATION paves the way to greater profits.

By improving the quality of your product, and keeping it up to standard it enables you to broaden your field and add new patrons.

But these results are possible only when the Refrigerating Equipment is correctly designed and properly installed.

We are constantly increasing our sales by reason of the excellent performance of existing YORK Plants.

We can serve you equally well. Write us for information and prices.

Uniform High Quality

Uniform high quality, which is so necessary in cold storage insulation, does not just happen. It results only from the careful selection of materials, scientific manufacturing methods and the rigid inspection of the finished product.

This shows sheets of Nonpareil Corkboard, 1, 2, 3, 4 and 6 inches thick, sawed through the middle. Notice the uniform structure in all thicknesses.

The uniform high quality of

Nonpareil Corkboard Insulation

For All Cold Storage Rooms

is obtained by using only the best cork waste produced, the larger part of which comes from our own plants in America and abroad. All of the granulated cork is carefully screened to take out the fine particles, dust and other foreign matter, which decrease the strength of the corkboard. The baking is done in scientifically constructed ovens, thus ensuring uniform and thorough baking in all thicknesses. This is a most important operation since corkboard that is improperly baked will not stand up in service. The edges, ends and sides of every sheet are trimmed and sanded by machinery, making them uniform in size.

Finally, each finished board is inspected four times before it leaves the factory, thereby assuring the purchaser that his Nonpareil Corkboard will have the same uniform high quality that has earned for this material the title of "The World's Standard Cold Storage Insulation."

Literature and Samples on Request.

Armstrong Cork & Insulation Co., Limited 504 McGill Bldg. Montreal, Que.

Also manufacturers of Nonpareil Cork Covering for cold pipes and tanks; Nonpareil Insulating Brick for boiler settings; Nonpareil High Pressure Covering for steam lines; Nonpareil Cork Machinery Isolation for deadening noise of fans, motors and pumps; and Linotile for floors in offices and residences.

DOORS

For Cold Storage and Freezer Purposes Either Standard or Fireproof

JAMISON'S "JONES" and "NOEQUAL" doors are SUPERIOR because:

1st—Only the best materials are used in their construction.
2nd—We use heavier materials. Result: Longer life and increased efficiency.
3rd—Our doors are built with double and triple seals of contact—others have but one.
4th—Our Automatic Self-Tightening Fastener is the only truly AUTOMATIC and SELF-TIGHTENING Fastener on the market.
5th—Our ADJUSTABLE SPRING Hinges mean the door is always properly seated in the frame, making sagging impossible.

Write for General Catalog No. 7, illustrating and describing both "Jones" and "Noequal" doors, windows, ice doors and chutes, etc.

20 K.V.A. geared alternator for night lighting or isolated plant work.

Moderate Speed Alternators

THERE are many advantages in using moderate speeds for turbine-driven alternators, including simplicity, reliability and a construction that can be taken care of and repaired by ordinary operating men. Higher efficiency is also obtained in the turbine by allowing it to run at its best speed, which in certain sizes is far above the speed generally prescribed for the alternator by the frequency.

For this service we recommend the De Laval Double-helical Speed-reducing Gear, as shown in the accompanying illustration. The turbine can be suited for any steam conditions, as receiving steam at boiler pressure and exhausting against back pressure, to atmosphere, or to condenser, or running upon low pressure steam, or both low pressure and high pressure steam, or it can be modified to bleed steam for heating, drying or industrial purposes.

MARSH and AMERICAN

Steam and Power Driven Pumps and Air Compressors

Marsh and American Pumps are especially adapted for long, hard service because they are *extra heavy* in design and of *extremely rigid construction*. Every unit is built amply strong to withstand 24-hour-a-day service and to stand up under any unforeseen strain which may be placed upon it. Piston rods on the steam pumps are extra large and made of solid bronze. The water ends are equipped with heavy cast bronze removable bushings.

This superior construction not only insures continuous and satisfactory operation, but practically *eliminates expensive shut-downs*. Marsh and American Pumps are the product of over 25 years' experience in the design and construction of high grade pumping machinery. Over 135,000 in actual service throughout the world.

The AMERICAN-MARSH LINE OF CENTRIFUGAL PUMPS is composed of both single and double suction types which are designed for heads up to 125 feet. They are equipped with wide ring oiled bearings and the single suction type has overhanging casing enabling the discharge to be taken at any angle desired.

"I have about 25 Davis Traps of various sizes in service, the majority of them for 22 years. I will gladly recommend them at all times," wrote H. F. Hustedt, Chief Engineer, Tulane University, New Orleans, when ordering his first repairs.

Possibly all Davis Traps would not last that long without repairs. Much depends on the operating conditions. On some installations they last longer than on others. But all Davis Traps have Tobin Bronze seats and valves—a hard, tough metal from which long service may be expected.

And when these vital parts of the trap do wear out, they may be easily renewed at slight expense.

We make Pressure Regulators . Balanced Valve . Float Valve . Steam Trap . Back Pressure Valve . Exhaust Relief Valves . Stop and Check Valves . Pump Governors . Damper Regulators . Radiator Air Valves . Emergency Stop Valves.

A High Example of Faith in Advertising

WE are quite accustomed to the idea that advertising is more highly developed in the United States than elsewhere. We are prone to assure ourselves that American business have a stronger faith in advertising, a clearer understanding of its powers, and a higher efficiency in its use than is possessed abroad. We have been told so, often enough, by advertising men from other countries, so our belief is not attributable soley to egotism. Since the war began, however, England has been setting some examples of advertising which are not easily duplicated.

We have referred many times to the British Government's advertising for soldiers and for subscriptions to the war loans—an unprecedented and extremely profitable use of advertising on a tremendous scale. We have noted many instances of British concerns which have made far-sighted investments in advertising to protect their good-will under adverse circumstances. And now comes the British automobile industry with an example of faith in advertising which puts to the blush some of our American advertisers who are "oversold"—and cancel their advertising orders in consequence.

If it takes a high degree of faith in advertising to advertise when the factory is oversold, what about the faith which continues to advertise when it is practically impossible to sell any goods at all? That is just about the condition of the British automobile industry. In the first place, every available automobile factory which is not making cars for the army is making war munitions. There is an embargo upon the importation of pleasure cars from other countries. Private owners of automobiles are under an allowance of six gallons of gasoline per month. Sir Hedley Le Bas, the official advertising manager for the Government, is placarding the country with such warnings as: "You are helping the Germans when you use a motor car for pleasure." According to a special investigation sent by *Automobile Topics,* the retail trade is absolutely paralyzed. It is not only impossible to get cars, but to sell those cars which are already on hand. Yet, in spite of such discouraging circumstances, the British newspapers and magazines continue to carry automobile advertising.

The investigator above referred to specifically mentions Willys-Overland, Limited, Daimler and Wolseley as advertising for "after-war" business. Dunlop and Michelin tires are featured almost as prominently as ever. "The day is steadily drawing nearer when we shall resume the production of motor carriages for private owners," says a piece of Daimler copy, and when that day comes the company expects to occupy the same high place in the public mind which it had before the war began. It is using advertising as the best possible insurance against public forgetfulness.

The British automobile industry is setting a high standard of faith in advertising, and understanding of its true functions. American advertisers cannot afford to be too complacent over their "leadership" in the face of such examples as these—*Printers' Ink.*

MAIN BUILDING OF THE UNIVERSITY OF TORONTO, NORTH OF AND FACING THE CAMPUS.

Engineering Laboratories of the University of Toronto

By Robert W. Angus, B.A. Sc.*

The growing recognition of the part played by technical education in national development imparts more than passing interest to the instruction plant by means of which the rising and future generations of this country's engineers are receiving knowledge. A study of the equipment described herewith, should convince even the casual critic that the requirements of engineering education have been recognized and met in a capable manner with a full breadth of vision, a desirable consummation in view of future world trade developments.

THE first engineering laboratory in Toronto was formally opened on February 24th, 1892, in the School of Practical Science, which is now the Engineering Building of the Faculty of Applied Science and Engineering of the University of Toronto. This laboratory consisted of three departments: First, the department for testing materials of construction. Second, the department for investigating the principles governing the application of power, which department included the steam laboratory, the hydraulic laboratory and the electrical laboratory. The third department was an astronomical and geodetic laboratory.

In the steam power department there were two boilers, the larger of 50 h.p capacity, a 50 h.p. Brown engine with condensers and pumps, and a machine for measuring journal friction and for testing lubricants.

The hydraulic division contained a three-throw pump driven from the Brown engine, a large impulse wheel, and two large tanks for orifice and weir experiments.

Initial Equipment

This equipment served very well at the beginning; there were not many students and thus a large number of pieces of apparatus was not necessary, and the apparatus actually installed was so well selected and suited the purpose so well that much valuable instruction was given on the machines mentioned.

As the work expanded and the number of students increased, small additions were made, but up to the time the writer was appointed demonstrator in this work in 1898, the only additions were two reaction turbines, neither of which was set up for operation, and a crude type of centrifugal pump, together with tanks for calibrating the orifices and weirs already mentioned.

During the past decade great advances have been made in the development of power, more especially in Canada, where we have been appreciating to some extent the value of our water powers. The gas engine has also been brought to a high state of perfection and suction gas has presented such great possibilities as to make it an important source of power.

Further, the work of the Engineering Faculty has been recognized by the people of the province in such a way that the attendance has increased by leaps and bounds.

For these and other reasons it has been necessary to increase steadily the equipment of the power department to illustrate the modern methods and also to provide sufficient apparatus for the increased number of students.

As the number of pieces of apparatus increased the available space became more and more crowded until during the last few years it has been difficult to carry on the work successfully. The steam laboratory had been placed in a comparatively low basement and the moisture and heat produced by the steam made the working conditions very bad.

After careful examination of the whole question, the Board of Governors of the University decided in June, 1908, upon the erection of a new building to accommodate the laboratories for steam, gas and hydraulic work and also for all general mechanical engineering, and the building described in this article is the result.

The money appropriated for the building as erected was between $85,000 and $90,000 and for new equipment approximately $22,000, although most of the apparatus which had been installed in the old laboratory has been moved in, so that the total value of apparatus and equipment in the new building would considerably exceed the $22,000 mentioned above.

New Laboratory

The building about to be described contains the laboratory for steam and gas engines, steam boilers, refrigerating machinery, belt and oil testing, and other similar work, and also that for hydraulic work of various kinds. It is built of white brick with white stone trimmings.

*Professor of Mechanical Engineering.

and consists of two parts divided by a wall running east and west, the part to the south of this wall having but one floor, while the part to the north has three floors.

When the building was first under consideration a number of very difficult problems presented themselves, partly in the way of finding sufficient room in already overcrowded grounds, and partly in the way of making the building harmonize with the other University buildings. In order to carry on the instruction required, a boiler room was necessary, which had to be placed on the outside of the building in order to facilitate the delivery of coal and the removal of ashes. Then, too, there was the problem of stacks, two of which have been provided for experimental purposes and the necessity of good light and large rooms, so that it was difficult to make the building look attractive. The architects considered the question with great care and arranged a scheme by which the boiler room and other unattractive parts will be eventually hidden when the entire group of buildings for the Faculty of Applied Science is completed.

The view on this page shows the building as it will finally appear. The front will be to the west and it will face on the main University road which runs north from College St., directly opposite University College. To the north of the building it is proposed in future to run a cross road east from the one above mentioned, the new road separating the Mechanical Laboratories and the building which will in time replace the present Engineering Building. At present there is only a very narrow passage between the two buildings. On the south the building will be connected to the future extensions to the Chemistry and Mining Building, which extensions are to be so planned that almost the entire south side together with the boiler room, which is now exposed, will be hidden.

The building will thus have a fine appearance and will with the Chemistry and Mining Building form a fine, large block quite in keeping with the nature of the work being done by this Faculty of the University.

Owing to the other pressing needs it was felt by the Board of Governors that it would be impossible to erect the entire building at the present time and as laboratory accommodation had to be provided the part containing this was erected and a reasonable number of class rooms provided in it, while the front part, which will contain more rooms of this nature, has had to be omitted for the present.

THERMODYNAMIC LABORATORY—SUCTION GAS PRODUCER PLANT.

The Thermodynamic Laboratory

Beginning with the space devoted to the heat engines and general mechanical work, we enter the Thermodynamic Laboratory. This laboratory occupies with the boiler room, the whole south half of the building and exclusive of the latter is 156 feet long by 60 feet wide with roof light throughout, there being no windows in any of the walls. It is divided into two parts, one being 40 ft. wide and the other 20 ft. wide, running the entire length of the room. The wider part has a clear height of 23 feet at the sides, being considerably higher in the centre. The narrower part has a clear height of 12 feet, and is divided up into smaller parts, there being eight small rooms, to be described later, and a space for delivery and unpacking of goods. The light is obtained from the roof and is as near perfect as can be expected. The ventilation is also very good being obtained by opening windows in the roof, a method which works so well that the building can be kept quite cool even with all the machines operating at once.

Internal Combustion Engines.—The equipment in the two parts of this laboratory may now be described in some detail, beginning with that in the larger part. The west end of this has been devoted to gas, oil, and other internal combustion engines and the equipment consists of a 10 h.p. engine built by Fielding

NEW LABORATORY OF FACULTY OF APPLIED SCIENCE CONTAINING STEAM, GAS AND HYDRAULIC EQUIPMENT.

& Platt, of Gloucester, England. This engine has a cylinder 7 in. in diameter and 14 in. stroke and has been specially built for experimental work. It is designed for variable compression, so that it may be adapted for use with different classes of fuels; and it is further equipped with three types of igniting gear, viz.: hot tube, high tension electric and a magneto gear, an arrangement being made so that the point of ignition may be varied at will while the machine is running. There is also a convenient method of varying the speed, and the use of heavy fly-wheels prevents great speed fluctuations at different speeds and loads. The engine is also fitted with vaporizing apparatus so that it may be run with oil, and has properly designed valves for the use of suction gas.

THERMODYNAMIC LABORATORY—GENERAL VIEW FROM WEST END.

Adjacent to this engine is a larger one built by the National Gas Engine Co., Ashton-under-Lyne, England. It has a cylinder diameter of 9 in. and runs at a normal speed of 200 revolutions per minute, giving 22 h.p. on city gas. This machine is a very fine sample of a gas engine, being exceptionally heavy and having two massive fly-wheels which give steady speed. It has variable compression as in the case of the Fielding & Platt engine, and is designed for the use of either city or suction gas. It has only the magneto form of igniter, but the point of ignition may be altered without stopping the engine, which is noiseless in operation.

As already explained, both the above engines may be operated by city or suction producer gas. In the former case the gas is drawn directly through a meter where it is measured. When the suction gas is used the latter is drawn from a producer in the small room in the south-west corner of the building. This producer, which was built by the Canada Foundry Co., of Toronto, consists of a generator complete with vaporizer, two scrubbers, and an expansion box from which the gas is delivered to a pipe conveying it directly to the engine. It is arranged so that fuel consumption tests may be made with it and the action of the producer carefully and accurately studied.

Adjacent to the Fielding & Platt engine and on the north side of it a test floor has been arranged so that engines of fairly large size may be conveniently tested, and it is hoped that various firms will, from time to time, place some of their engines at the disposal of the laboratory for examination and research work, as it is believed that this will prove of mutual benefit to the manufacturer and the University. This test floor is at present occupied by one of the earliest types of gas engines built by the Otto Gas Engine Co., Philadelphia. The engine has given good service in the engineering building for nearly twenty years and is retained to give some idea of the development of the gas engine of late years and because of its historical interest. It is one of the slide valve type of engines with the old form of gas flame igniter, and is in good condition for test and comparison with the newer machines.

The space immediately in front of the engines just mentioned is used for two smaller test floors for gasoline and other similar small engines. Each floor is three feet square and has adjustable slots by which any small engine may be accommodated.

A marine gasoline engine with a cylinder 6 in. diameter and 6 in. stroke has been given by the Canadian Fairbanks Co., Toronto, at a nominal price and has been placed on one of the test floors mentioned and set up for experiments. This engine is to be equipped with an optical indicator made by Dobbie, McInnes & Co., Glasgow, so that its action may be accurately studied.

On the south side of the large room is an Ericsson air engine which serves to illustrate the action of this type of engine and give figures on its economy. It is arranged to be run by city gas and a brake has been arranged to measure the brake horse-power at the same time as the indicator diagrams are taken. The efficiency of the machine as a pumping engine may also be found by allowing it to lift a measured quantity of water against a measured head.

Other Apparatus.—Proceeding farther east along the large room there is seen a fan on which experiments on its efficiency are to be made.

A little farther down is a slide valve model. This model is very complete, and has been constructed so as to give results on almost any design of simple slide valve or link motion. The length of connecting rod is adjustable, as well as the angle of advance and throw of all eccentrics, the length of eccentric rods, radius and point of support and suspension of the link, etc.

There is also a journal oil tester built by Riehle Bros. of Philadelphia, and having various adjustments. The journal used in the machine is a full-sized railway car journal, and the design is such

THERMODYNAMIC LABORATORY—DE LAVAL STEAM TURBINE WITH WILLANS VERTICAL AND LEONARD HORIZONTAL ENGINES IN BACKGROUND.

that the actual pressures and speeds occurring in practice may, within limits, be obtained. The friction of the journal is conveniently read off on a scale beam.

The Steam Engines.—We pass on now to the steam engines. The first of these are two of comparatively small size which were presented to the Laboratory by Messrs. E. Leonard & Sons, London, Ont. These engines are used almost exclusively for exercises in valve setting, and have cylinders 6 in. and 7 in. in diameter respectively, and 8 in. stroke, but have different types of slide valves. The one to the south has the ordinary D form of valve and a special design of eccentric may be independently varied. The other engine has a special type of inside admission valve, which is partially balanced and so designed that the engine may be operated without the steam chest cover and thus show the motion of the valves; this engine has an eccentric of the same type as the one just described.

THERMODYNAMIC LABORATORY—McEWEN AND LEONARD—BALL ENGINES WITH CONDENSING PLANT AT LEFT.

Both of these engines are fitted with throttling governors and suit the work for which they are designed exceptionally well, the kindness of the donors being much appreciated.

Next to these is a 15 h.p. de Laval steam turbine, built by Greenwood & Batley, Leeds, England. As is the case with most of the other machines, this turbine has been specially arranged for experimental work and has six nozzles altogether, some of which are for non-condensing operation and the others are used when running condensing. The rotor of this turbine runs at a speed of about 24,000 revolutions per minute, the power shaft running at one-tenth of this speed. This turbine has been found very useful as an experimental machine.

Behind the turbine is a Willans vertical, high-speed compound engine. This machine was purchased to drive the turbine pump in the old laboratory, but with the building of the new one an extra pump had to be installed so that a larger engine had to be purchased to supply the necessary power and the Willans engine became available for experimental work. It is of the high-speed type, having a normal speed of about 460 revolutions per minute, and developing at this speed 75 h.p. with a steam pressure of 125 pounds per square inch.

The design is rather peculiar, as there is no valve gear evident externally. The piston rods are hollow and the piston valves are operated by eccentrics forged solid to the crank pin. In this particular engine there are two high pressure and two low pressure cylinders, the high pressure cylinders being above the corresponding low pressure ones; all are single-acting, and in order to prevent shock on the crank at the end of the stroke there is an air piston below each pair of cylinders, the pressure of the air compressed by it being sufficient to make a continual downward thrust. The crank bearings have no upper cap and require none for the above reason.

The steam cylinders are respectively 10 in. diameter and 14 in. diameter, and all pistons have a stroke of 6 in.

Engines of this type have met with great favor in England because of the low steam consumption, a paper by Mr. Willians read before the Institution of Civil Engineers in April, 1893, giving some very valuable information along this line.

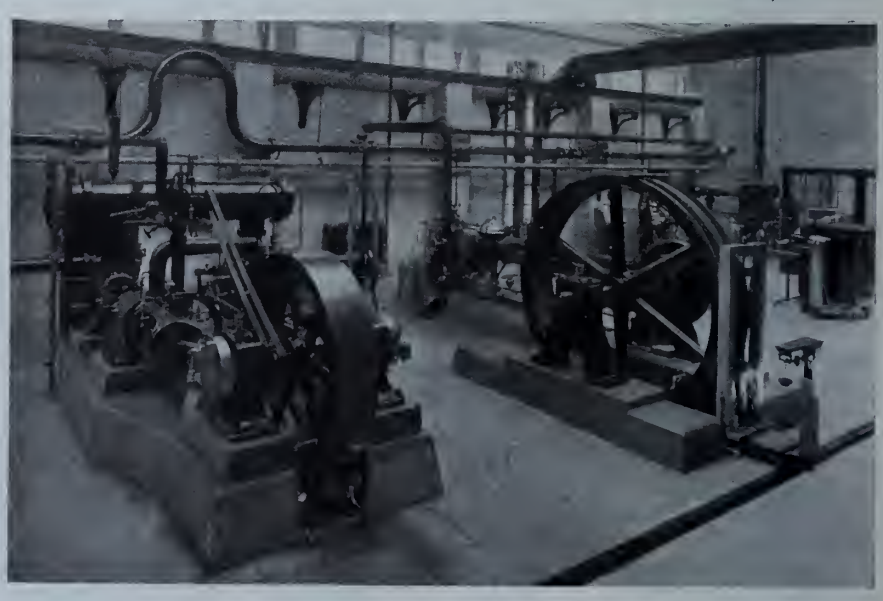
A passage leading to the door separates these engines from the McEwen high-speed horizontal engine. The cylinder is 8 in. diameter and 7 in. stroke, giving 18 h.p. This engine has a good form of shaft governor, so that it is well adapted to instruction in the use and action of such governors, as well as providing good indicator practice. As it is connected like the other machines to the surface condenser, tests on the economy of the machine may be conveniently made.

The Leonard-Ball tandem compound engine is also provided with a shaft governor of different type from the one mentioned above. This engine is horizontal and has cylinders 7 in. and 12 in. diameter by 10 in. stroke, and will thus develop about 29 h.p. at 250 revolutions per minute.

There are two types of valves in the engine, the one in the high-pressure cylinder being a Ball valve with double inside admission. The valve is partly balanced, gives rapid cut-off, and on account of the double parts has a comparatively small travel. In the low pressure cylinder a balanced D slide valve is used.

This engine provides instruction in the tandem type of machine as well as practice with a shaft governor.

Next to the engine just described is the air compressor, a machine built by the Canadian Rand Drill Co., Sherbrooke, Quebec, and purchased through Mr. Haight of the class of '96 at one-half the actual commercial selling price. This machine is of the cross-compound, steam-driven, two-stage type, having the low pressure air cylinder arranged tandem with and behind the low pressure steam cylinder, and the high pressure steam cylinder in front of the high pressure air cylinder. The steam cylinders are respectively 9 in. and 16 in. diameter, while the air cylinders are 9 in. and 14 in. diameter, all having the same stroke of 12 in.; the normal speed is 160 revolutions per minute and the rated capacity 340 cu. ft. of free air per minute,



THERMODYNAMIC LABORATORY—CANADIAN RAND AIR COMPRESSOR AND BROWN STEAM ENGINE.

with a steam pressure of 125 pds. per sq. in.

The fly-wheel is arranged with inside flanges so that a brake may be applied to it, and by disconnecting the air cylinlers the whole may be run as a cross

VIEW OF THERMODYNAMIC LABORATORY FROM EAST END.

compound steam engine. Both steam cylinders are provided with Meyer cut-off gear, giving considerable elasticity.

The low pressure air cylinder has Corliss inlet gear and pressure gauges and thermometers are arranged for experiments of various kinds.

An air receiver is installed and piping runs to the mining building, delivering air when required to drive a rock drill.

This machine is of great value and usefulness and forms a very good piece of experimental apparatus.

When the engineering building was opened it contained a 50 h.p. Brown automatic cut-off engine built by the Polson Iron Works, Toronto, and this engine has been set up again in the new laboratory. It is of special design for experimental work and has jackets on both heads and on the barrel, all jacket drains being separate in order that the condensation in each part may be independently determined. The clearance volumes in this particular machine are also made specially small, and it runs quite economically.

The Steam and Exhaust Piping.—An examination of the photographs will show the general arrangement of the steam piping. It consists of a single line of 5-in. pipe running through the boiler room and about 90 ft. along the wall of the Thermodynamic Laboratory, also of a 3½-in. pipe running from the northerly boiler up to the Brown engine connection. The latter pipe is designed so that it is possible to run a complete engine and boiler test on the Brown engine and the one 50 h.p. boiler. Connections are also made so that this boiler may deliver steam to the 5-in. pipe and the Brown engine may also be arranged to draw from the same pipe.

The 5-in. pipe has two large expansion bends, the one near the Brown engine being distinctly visible in the photographs. All connections on this line are flanged and each engine draws its supply from the top of the pipe, thus avoiding water from drainage and condensation.

All engines are arranged to run either condensing or non-condensing, two surface condensers with independent air pumps being installed for the former condition of operation. There are two 6 in. exhaust pipes, one of which is connected to the condensers, the other through the heater to the atmosphere. Both of these are arranged with flanged connections and the system is so designed that by the removal of a few bolts any engine may be changed from the atmospheric exhaust to the condenser in a very short time, it being only necessary to change one blank flange and turn an elbow through 180 deg. The operation is thus accomplished without the use of valves and the measurement of the condensed steam becomes at once accurate. The system also permits the running of almost any pair of engines condensing, and at the same time the operation of all the other engines non-condensing. Proper drainage is provided for all piping, and it has all given perfect satisfaction up to the present time.

The cooling water piping is shown below the steam piping, but possesses no special features.

Brakes.—The writer believes that brakes should be of the simplest form possible so that students get accustomed to the handling of the cheapest and most accessible types. The brakes used are, therefore, rope brakes or else simple forms of the Prony brake, the wheels being generally provided with inside flanges so as to avoid annoyance from the cooling water.

The remainder of the space in this part contains a test floor, which permits any engine submitted for test to be easily set up and run either condensing or non-condensing. There is also a space for the testing of injectors, these being arranged in a convenient and neat pipe stand ready for operation.

At the end of the room is a Cochrane feed water heater purchased from the Canada Foundry Co., Toronto.

Some space has been left at this end of the room for expansion, and it is hoped that in the near future a triple expansion engine will be installed here.

Small Laboratory Rooms.—The narrower southerly portion of the Thermodynamic Laboratory (with the exception of the two end bays, which are used for delivery and unpacking) is divided into eight small rooms for special work of various kinds. The first two rooms are connected by a door, and are used as a small repair and instrument-making shop, in which special apparatus is made as required. This shop contains a new 20-in. Bertram engine lathe of modern construction built by John Bertram & Sons, Dundas, Ont. There is also a 20-in. McDougall drill, an emery wheel and a wood-turning lathe, together with a good equipment of tools. The shop is driven by a Westinghouse motor.

The third room will contain the apparatus for testing various machine elements and the methods of power transmission. For this purpose a tor-

Thermodynamic Laboratory—Refrigerating Plant with Test Chamber for Building Materials on Left.

sion dynamometer has been purchased from J. Amsler-Laffon & Sohn, Schaffhausen, Switzerland, which may be used for the transmission of any power not requiring over 540 ft. pds. twisting moment. As the machine may be safely run

at high speeds its possibilities in the way of power transmission are fairly great, and it thus serves as a very flexible instrument. This instrument will be used to deliver a measured quantity of power to a belt or rope or any form of bearing or machine element, and the efficiency of the transmission or element may be directly determined by absorbing the power by a brake at the driven end.

HYDRAULIC LABORATORY—ESCHER, WYSS AND GWYNNE PUMPS DRIVEN BY BELLIS & MORCOM ENGINE.

The fourth room contains a refrigerating machine of three tons capacity, built by the York Manufacturing Co. of York, Pa. It is of the ammonia compression type and the horizontal steam engine and vertical compression machine are connected to the same crank. The complete accessory equipment has been provided and arrangements made for indicating the steam and ammonia cylinders and for taking the temperature at every desirable point in the plant.

The next room has been set apart for instruments, and in it are kept all of those used in both the Thermodynamic and Hydraulic Laboratories. All instruments are given out to students on application by ticket and are charged up against the one receiving them. When an instrument is returned it is examined and if in proper condition is put in its place, but if found to have been damaged by the student, the cost of repair is charged against him. By this system careless handling or loss of instruments is avoided.

The sixth room is used as a third year study room, while the seventh is to be used for the testing of lubricating oils and the determination of the heating power of gases and fuels of various types. A Sargeant gas calorimeter has been purchased and is to be used in this room.

The last room is occupied by the suction gas plant, described earlier in this article.

Just in front of these rooms and secured to the crane piers a number of tables have been placed, on which work on gauge and indicator calibration may be carried out, the gauge calibration being done by Crosby gauge testers, while the indicator springs are calibrated by means of steam supplied at various pressures.

The whole of the larger part of this laboratory is served by a three-ton travelling crane of about forty feet span. This crane is operated by hand, and has proved of inestimable value in the placing and handling of the different pieces of apparatus.

The Hydraulic Laboratory

The Hydraulic Laboratory occupies the north half of the building, and is located in the basement and ground floors, each of which is 40 ft. wide by 113 ft. long. The light for this laboratory had to be obtained from the north and east, and as only one large window could be placed in the east end, the north light had to be depended on almost entirely. Large windows running up the full height of the two laboratory storeys were designed, which take up three-quarters of the entire side of the building. This gives a good architectural effect, and while not giving as good light as is obtained from the roof in the Thermodynamic Laboratory, yet it is quite satisfactory.

On account of the large area of glass exposed to the north, trouble was anticipated in the way of heating the building, and arrangements were made to put double windows throughout, which, however, have not been necessary.

The lower storey or basement is 18 ft. high, and contains the well, the pumps and the engine for driving them, the measuring tanks used for calibrating the orifices and weirs above, several large troughs and the main part of the piping for the entire laboratory, while the upper floor, which is 15 ft. high, contains the orifice and weir tanks, the experimental centrifugal pump with its weir tank and motor, the various pipes for friction experiments, the meters, and also the various types of turbines and other apparatus.

Beginning with the top floor at the west end, part of the space had to be left clear for a hoist hole, the first piece of apparatus being a centrifugal pump of special construction for experimental work. This pump was designed along theoretical lines, and has carefully polished vanes on the runner; it is mounted on a weir tank so that the discharge may be very easily measured, the various heads under which it is operated being obtained by throttling. The pump is driven by a variable speed motor, by means of which the power put into the pump may be determined and its efficiency readily obtained. The arrangement has been found very satisfactory, as it gives the student an opportunity to study the effect of variations in speed, discharge, pressure and efficiency of the machine.

Adjacent to this are two orifice tanks and a weir tank used mainly for instruction in the use of orifices and weirs. Various sizes and shapes of orifices are inserted and operated under several heads as measured by hook gauge. The water is discharged through 6-in. pipes into the calibrating tanks below, of which there are six, two for each orifice and weir, each tank having a capacity of about 50 cu. ft.

These calibrating tanks are of some interest, and have been carefully designed so as to be entirely operated by the movement of a single lever. When the lever is put in one extreme position, one tank is made to fill, its outlet valve being closed, while the outlet valve of the other tank is at the same time open. For the small discharges the tank fills so slowly that the upper surface is quite smooth and undisturbed, and, therefore, the exact height of the water in the tank, and consequently the volume of the water at the moment of dumping is easily observed, but where the discharges are large, the surface of the water in the calibrating tank is so disturbed that accurate observations of this kind are im-

HYDRAULIC LABORATORY, FRANCIS HORIZONTAL TURBINE COUPLED UP TO 5 FT. 6 IN. STANDPIPE.

possible. To obviate this trouble the mechanism is so designed that by moving the lever to an intermediate position the outlet valve on the other tank is closed, and the discharge turned into it, the water surface in the first tank coming to rest at once its height is easily observed, after which the lever is pushed to the other extreme position, the outlet valve of the first tank being thus opened without disturbing the conditions in the second tank.

The quantity of water in the tank after filling may be found by direct weighing or by reading the level in an attached gauge glass.

The floor has been constructed with an opening protected by a rail, so that the student may observe the whole operation at one time and thus get a clear idea of the process of calibration.

In order that experiments on these tanks and orifices may be carried on without interfering with the other work, a large reservoir, provided with an overflow, has been placed above them, and from this they draw water. So long as there is enough water passing into the reservoir to cause some overflow the experiments may be carried on at various heads and discharges without difficulty.

From this reservoir a 1¼-inch pipe is also run to a hydraulic ram which can thus be operated under a head of about 10 ft. and with a drive pipe about 40 ft. long.

A three-inch Venturi meter has been installed on a pipe in which other meters will also be placed. This meter is rated by sending the discharge from it through one of the orifice tanks already described, using the coefficients determined by actual experiment.

A little to the east of the centre of the laboratory an elevated platform about 25 ft. long and 7 ft. wide has been erected for the impulse turbines. At present two turbines are in use, one a Doble wheel made by the John McDougall Caledonian Iron Works, Montreal. This is a very well finished wheel of 12 in. dia., and as it has glass sides the action of the water may be very conveniently studied. The needle regulating nozzle gives a very perfect stream.

The other machine is an 18-in. wheel made by the Pelton Water Wheel Co., and although not so well constructed, it represents a very common class of water-wheels in use to-day.

The water used by these turbines is measured by passing it through a weir tank and then back to the pump well. For the use of these turbines it is possible to get a discharge of 1 cu. ft. per sec. against a maximum head of about 500 ft.

At the east end of the room is a large stand-pipe 32 ft. high and 5½ ft. dia., supported on a stand in the basement so that it reaches up into the roof of the building. This stand-pipe is used as a reservoir for the reaction turbines and also for any experiments requiring constant but not very high heads. This stand-pipe has a 14-in. nozzle on each side for the attachment of turbines and also a large nozzle 30 in. dia. on the front so arranged that orifice plates and tubes of various sizes may be attached and experiments made at higher heads than is possible in the open orifice tank. The water is delivered to the stand-pipe through two 8-in. pipes near the bottom and by a convenient arrangement of baffle plates there is no trouble caused by the surging or eddying of the water.

In front of this stand-pipe is a large weir tank 20 ft. long by 6 ft. wide, which is arranged with a sharp crested weir 4½ ft. wide with end contractions. This plate may, however, be changed so that weirs of different sizes, with or without end contractions, may be easily inserted. The total depth of the tank is 3 ft. 9 in. and the depth of water below the crest of the weir is 2 ft. 3 in.

The weirs used in this tank may also be calibrated by means of a pair of measuring tanks in the basement, each holding approximately 240 cu. ft. and both being connected to the weir tank on the down stream side of the weir by 12-in. galvanized iron pipes. Hydraulically operated valves are to be used in connection with these calibrating tanks and are so designed that a single lever is made to do the whole operation of filling emptying as in the case of the smaller tanks already described. This lever, as in the former case, has three positions when operating, the extreme positions indicating that one tank is filling and the other emptying, while the intermediate position is used when both discharge valves from the tanks are closed and one of the tanks is filling. It is believed that very accurate co-efficients can be determined by this method.

There are three reaction turbines available for testing. The smallest one has a 6-in. runner and was made by Wm. Kennedy & Sons, Owen Sound, Ont. It has been set up in a steel penstock and connected to the stand-pipe by a 14-in. steel pipe containing two elbows. This pipe is to be used for experiments on the flow through elbows, the conditions being examined by a Pitot tube. This 6-in. turbine has been operated under a total head of over 25 ft. including about 5 ft. in the draft tube. The horse-power is measured by Prony brake and the discharge is determined from the 4½ ft. weir.

A 9-in. McCormick turbine with cylinder gate has not been set up but is left to give the student practice in the measurement of such wheels and to enable him to study the forms of the vanes.

The latest turbine to be installed is one purchased recently from the noted hydraulic firm of Escher, Wyss & Co., Zurich, Switzerland. This wheel, of the horizontal Francis type, has a well designed spiral casing and a runner nearly 14 in. dia. The gates are of standard design, operated through a ring by a hand wheel on the casing. A conical draft tube over 7 ft. long is used and the wheel will deliver 10 H.P. when supplied with 6 cu. ft. of water per sec. at a head of 20 ft. As this wheel is of the very best construction it forms an excellent addition to the experimental equipment.

BOILER ROOM—ONE 100 H.P. AND TWO 50 H.P. BABCOCK & WILCOX WATER TUBE BOILERS.

The maximum quantity of water available for these reaction wheels is about 6 cu. ft. per sec.

Along the north side of this floor near the windows arrangements are made for the testing of the friction in fire hose and iron pipe. A 2½ in. iron pipe 50 ft. long has been set up, also a 50 ft. length of fire hose, and the frictional losses are determined. The flow in the iron pipe is also studied by the Pitot tube, and curves showing the distribution of the velocity are plotted.

The basement contains, in addition to the orifice and weir calibrating tanks already mentioned, the well and pumping plant. All water used in the laboratory is drained back to a large well from which it is pumped into the system and used over and over again.

There are two sets of turbine pumps used for this purpose, one of which was built by Messrs. Gwynne, London, England, and the other by Escher, Wyss &

Co., Zurich. Each set consists of two two-stage pumps fastened to a common bed plate and driven by a single pulley, couplings being arranged so that either pump may be separately operated. Further, the two pumps on the one base are piped together in such a way that they may be made to deliver into the piping in three ways, viz., (a) separately, (b) in series, (c) in parallel. A connection is also designed to connect the discharge from the Gwynne pump to the suction from the Escher-Wyss pump, putting the two sets in series for very high pressure work.

Each of the Gwynne pumps will deliver 1 cu. ft. per sec. against 125 ft. head, while the other pumps have the same capacity against 150 ft. head, the discharge at lower heads being, of course, much greater.

As suitable piping has been arranged in the laboratory, it may thus be seen that the whole arrangement of the plant is very flexible, permitting (a) the operation of the four pumps separately, thus allowing four absolutely independent experiments at one time; (b) the operation of the two sets separately on separate experiments; (c) the operation of the two sets in series for high pressures and moderate discharges as are required in fire streams and impulse turbines, giving 1 cu. ft. per sec. at 500 ft. head; (d) the operation of the two sets in parallel giving about 6 cu. ft. per sec. at the heads available in reaction turbine work in the laboratory.

The pumps are of modern design, the Escher-Wyss set having been installed quite recently. They run at speeds of 1,300 and 1,400 revs. per min. respectively, and are belt-driven from a jack shaft placed on the floor, vibration of the building being thus entirely avoided. The jack shaft is driven by a Belliss Morcom engine of 130 H.P. running at 530 revs. per min. This engine is a very fine piece of workmanship and runs quietly and without vibration. The exhaust from the engine is used to heat the building.

Arrangements are being made for the insertion of a transmission dynamometer in the Escher-Wyss pump drive so that its efficiency may be determined with greater accuracy than can be obtained by indicating the engine.

A large trough 6 ft. wide, 4 ft. deep and 110 ft. long has been provided in the basement which is used for the rating of current meters and tubes and other work of this nature. It is believed that this will be especially useful in view of the rapid power development going on in Canada at the present time.

There is sufficient space still left for further expansion.

The Boiler Room

This room contains three Babcock and Wilcox boilers, all built for 200 lbs. pressure.

The 100 H.P. boiler is provided with a superheater while the two 50 H.P. boiler have been set up independently and one is arranged with a special type of setting so that valuable comparative results may be obtained.

A separate feed pump is provided for each boiler so that separate tests may be made on each one.

A steel breeching conducts the products of combustion to the stacks, of which there are two of brick, each 100 ft. high and 36 in. internal diameter. An arrangement of dampers allows these stacks to be operated at different powers on the same day and thus reliable experiments may be made on the capacity of each stack.

The room is light and airy, being 70 ft. long, 45 ft. wide and 26 ft. clear height. All the light is obtained from the roof and is very satisfactory indeed.

Offices and Study Rooms

AT the north-west corner of the building, immediately west of the Hydraulic Laboratory, there is a further space partly occupied by the stairways and halls and partly by other rooms. These rooms are as follows: In the basement the students' room with shower bath, on the first floor the professor's and the lecturers' rooms while the top floor is occupied by a lecture room and private lavatory.

An entire floor above the Hydraulic Laboratory is divided up into students' study rooms, a lecture room, a library, demonstrators' rooms, and students' lavatory. All of these rooms are comfortable and bright and the students' rooms are provided with convenient tables and a locked drawer for each person.

Artificial Lighting

The large Thermodynamic Laboratory is lighted by ten Nernst lamps, which are attached to the trusses and provide sufficiently good light to do any work required. The Hydraulic Laboratory is lighted by tungsten lamps, there being ten to each floor.

The remainder of the building, with the exception of the boiler room, which also has a Nernst lamp as well as incandescent lamps, is lighted entirely by incandescent lamps, which seem to give very good satisfaction so far.

Conclusion

This article would be incomplete without making mention of the work of Dean Galbraith. It was he who gave the writer his first real insight into the profession which he honors and it is on the foundation laid by him that the writer has built in striving to design a laboratory that shall give the future engineers the proper basic principles on which their life work depends. The teaching of principles is vastly more important than the teaching of a few facts, the desire to teach these principles in such a way as to make the practical application clear is a thing for which Dean Galbraith has always stood, and the writer's association with him and the engineering world have given him the desire to make the laboratories described such as shall be a real help to the student when he gets into active practice.

Acknowledgment is also made of the help given by the members of the staff in Thermodynamics and Hydraulics who assisted by many suggestions and by the sacrifice of much time in making the building and equipment such as it is.

It will be noticed that all of the units in the two laboratories are comparatively small and are such as can be handled with comparative ease. The writer believes this to be a valuable feature of such a laboratory, as the student can readily comprehend the whole machine at one time, and therefore does not lose the connection between the different observations as he is apt to do with the larger units where the parts are so much separated. The results obtained are, the writer believes, quite as valuable, from the point of view of the instruction to the student when obtained from reasonably small machines as from very large ones.

No machine in the laboratory is used for electric power or for any other than experimental purposes, so that all pieces of apparatus are always available for experiment or research.

OBTAINING DRAUGHT WITHOUT HIGH CHIMNEYS

IN ordinary practice, the use of the chimney is to cause a draught to make the fire burn, or in other words to cause the passage of a sufficient volume of air at a moderate velocity to supply oxygen enough to enable the fuel to be consumed to the greatest advantage, and incidentally to carry off the burnt (and unburnt) products arising through the combustion of the fuel. So far as it goes this is all right; but in very many cases it leaves much to be desired. To secure the most efficient heating it is necessary that the fuel should be reduced to its highest gaseous state—in the case of carbon this would in ordinary cases be carbonic acid—and to get to this stage it is necessary that large volumes of air must be drawn through the fuel at a comparatively low velocity. This is best done by means of exhaust fans of fairly large size, the discharge from which is passed through stacks of brushwood not too tightly packed together and kept damp by some simple method of water distribution and spraying.

A Moving Appeal.—"Yes," said the naive young person, "we invited three soldiers for dinner on Christmas Day. We felt we just had to, for mother said it was a crime to eat turkey at 42 cents a pound unless we had some sort of excuse for it. So we hunted one up quickly, and we never had such a delightful Christmas as we did entertaining three perfect strangers. What about them? Well, they stayed until nearly twelve o'clock, and I think they'd be here yet, smoking cigarettes, if one of them hadn't happened to be Scotch, and we suggested that they would have to be taking night cars very soon!"

Light, Heat, and Ventilation

HEATING AND VENTILATING RESIDENCES IN ENGLAND.

By C. T. Alfred Hanssen, A.M.I.C.E.

THE heating of a house, as pointed out, may be easily accomplished if ventilation be disregarded, and vice versa, the real trouble only beginning when an effort is made to combine heating with ventilation. The reason for the neglect and lack of development of heating systems in England is attributed to the peculiar weather conditions prevailing in the British Isles.

In most countries in Northern Europe and America the winter temperature is much lower than in England, and the cold is too deadly and dangerous to health to permit any neglect in the heating of houses, and there it is generally the ventilation that is neglected. In England, where the average temperature of the coldest month is well above freezing point, and where there has been no really cold winter during the last twenty years, it is the heating that is neglected and the ventilation that is encouraged. Although an immense amount of coal is used for heating our houses, it may be fairly stated that their average temperature is not much above that of the outside air, and although every inducement is offered to the air to enter our houses, by building them with open fire-places and large and leaky windows—often left open during the coldest weather—thin walls, and badly fitting doors, it is really a question whether our houses are, after all, much better ventilated than those on the Continent or in America.

Introducing Ventilation

Air, in common with all other substances, has that inertia which compels it to remain stationary unless it is acted upon by some force that causes it to move, and it is not, therefore, sufficient to provide openings for the air to enter; it is also necessary to provide some force to compel the air to move through the openings. If, for instance, there is a considerable difference between the temperature of the room and that of the outside air, every opening, however small, will have a current of air passing through it (and if the opening be large enough to examine it by means of a candle flame it can easily be seen that there is a lower current of cold air entering the warm room and an upper current of warm air leaving it.) A fire in an open grate will cause a column of warm air to rise through the chimney, and in this manner a large volume of air may be drawn through a room, but it is by no means certain that this air will ventilate the room. If the incoming air is colder than the air of the room it will probably sink down to the floor level, flow along the floor to the chimney, and pass out of the room without removing or displacing the vitiated air at the breathing level of the room.

Health Aspects

The difficulty of effective ventilation is therefore a double one: first, of causing the air to enter in such a way that it is not felt as a draught, and, secondly, of distributing the entering air over the whole room in such a manner that it really displaces the spent and vitiated air in the room. In bedrooms that are not, as a rule, heated, it is impossible to secure effective ventilation merely by opening a window, as the ventilation stops when the room is cooled down to the temperature of the outside air.

There is a widespread idea that cold air is healthy and that exposure to cold in chilly and draughty rooms hardens us and makes us better able to avoid the colds and catarrhs that are so frequent during cold weather. This, however, is one of these half-truths that are more dangerous than falsehoods. Vigorous exercise in the open air in places where the air is free from dust and smoke is undoubtedly most beneficial to health, and in this country there are very few days in the year when such exercise cannot be taken, but that is a very different thing from sitting or standing, almost motionless, in a cold room through which a current of cold air is passing. The air of our great cities is, especially during winter, very far from being of that purity which is most conducive to health, and even where it is admitted in a sufficient quantity and properly distributed through the whole room it is only a poor substitute for the air of the sea, field and forest. When, however, this air is admitted in such a manner that it forms only a cold current at the floor level, and is allowed to rush into a yawning chimney shaft a few feet above the floor, there cannot be the slightest doubt that ventilation of this kind is wholly injurious and deleterious to health.

Foreign Weather Conditions

Foreign cities generally show an increase in the death rate during winter, but the average temperature during each quarter has not been available to the author, and he has therefore only given examples from Paris and New York. In Paris open fires are used, but as people live in flats the houses are much more substantially built, and although the winter as a rule is somewhat colder than in London, the rise in the death rate is not so pronounced. In New York the winter is much colder than in London or Paris, but as the houses there are kept warm by stoves or radiators, the increase in the death rate is much less than in Paris or London. The conclusion, therefore, seems irresistible that although vitiated air undoubtedly is very bad for the health, cold air nevertheless is still worse, that during every cold wave in London as many people are killed as at the outbreak of an epidemic, and that is is a worthy object of sanitary engineers to persuade people to have their houses heated and ventilated in such a manner that the winter death rates should not be substantially higher than they are during the summer.

Ventilation.

Although the essential fact regarding the quantity of air required per person for effective ventilation is fairly well established, the quantity itself as stated by good authorities varies within very wide limits. Sir Napier Shaw, F.R.S., in Air Currents and Laws of Ventilation, demands as a normal unit 1 cubic foot per second per head, or 3,600 cubic feet per hour, while Molesworth's Pocket Book under "Ventilation" gives 300 cubic feet per hour for proper ventilation for a healthy man. The essential fact is that the atmosphere under normal conditions contains 4 parts of carbon dioxide per 10,000 parts of air, and that this proportion should not be unduly increased. The average quantity of air inhaled by an adult is about 16.6 cubic feet per hour, and the exhaled air contains 4.5 per cent. of carbon dioxide, or 450 parts per 10,000. The point in dispute is the quantity of CO_2 which may be allowed in the air of a room over and above the normal quantity of 4 parts per 10,000. If an excess of only 2 parts per 10,000 can be permitted then the quantity of fresh air required is $(16.6 \times \frac{450}{2} =)$ 3735 cubic feet per hour, but if, as others maintain, it is quite safe to go up to an excess of 25 parts per 10,000 then only $(16.6 \times \frac{450}{25} =)$ 300 cubic feet per hour are needed. The essential point in all systems of ventilation is that the incoming fresh air should be uniformly distrib- throughout the whole room, and

*From paper read before the Society of Engineers, London, England.

should, as far as possible, displace the vitiated air in the room, and for this purpose the incoming fresh air should have approximately the same temperature as the air in the room, as otherwise convection currents will cause it either to rise to the ceiling if it is warmer, or to fall to the floor level if it is colder than the rest of the air in the room. Under ordinary conditions the air exhaled from the lungs will by virtue of its higher temperature, rise towards the ceiling, although its high percentage of carbon dioxide makes it heavier than air of the same temperature. There is a critical point at about 80°F. when the exhaled air no longer rises but remains stationary at the breathing level of the room and, therefore, increases the difficulties of efficient ventilation.

The specific heat of air at constant pressure is 0.238 and one British thermal unit of heat will, therefore, raise $\left(\frac{1}{0.238}\right)$ 4.2 lb. of air 1°F. The volume of 1 lb. of air varies from 12.4 cubic feet at 32°F. to 13.1 cubic feet at 60°F. and at this latter temperature 1 B. T.U. will, therefore, heat about 55 cubic feet of air 1°F. The cost of heating a liberal supply of air to a moderate temperature is not, therefore, very heavy, and if suitable apparatus is provided for this purpose it is quite practicable to supply the full quantity of air demanded by Sir Napier Shaw at a very moderate cost.

Cost of Heating

The cost of heating the air can be estimated when we know the average temperature of the outside air, the proposed temperature of the house to be ventilated and the volume of air to be introduced into the house.

An average family consists of six persons and supposing them to require 3,600 cubic feet per head per hour, an average house should have a supply of 22,000 cubic feet of air per hour. To introduce this air into the house by means of open windows and open fires is not only a very clumsy method, but it is during the winter also a very expensive one. We may hope that one of the first results of national re-organization may be an abundant supply of cheap electric power and that this power may be obtainable at a rate of one penny per Board of Trade unit. A well designed fan with an efficient electric motor supplying the above quantity of air will then work 24 hours per day for about 1¼d. or 38s. per annum, and will save a great deal more than this value of coal.

Where the air supply is admitted to the room at a moderate temperature slightly cooler than the temperature of the room itself, and with an initial velocity of not more than two feet per second, the inlet openings should be of ample size, adjustable according to the number of persons present in the room and at the breathing level or about 4 ft. 6 in. above the floor. For ordinary rooms the outlet openings may be much smaller and as all impurities as a rule rise towards the ceiling, they should be there, and may conveniently be arranged as adjustable outlet-openings into the chimney-flue.

Heating.

The most convenient and most sanitary fuel for heating a house is undoubtedly gas, but in order to have gas heating as a practical possibility the cost of gas must be very materially reduced. One pound of coal yields about 14,000 B.T.U., and a ton of coal, therefore, yields 31,350,000 B.T.U., while calorific value of a cubic foot of gas may be at 535 B.T.U. A ton of coal is, therefore, equivalent to 58,700 c. ft. of gas and with gas at 3s. per 1,000 c. ft., this is equivalent to coal at £8 16s. 1d. per ton. Gas is, therefore, at present, far too expensive for continuous heating and can be used only for cooking and temporary heating of rooms used on special occasions.

If producer gas were added to the present supply, and the mixture used exclusively for heating, distributed more continuously under higher pressure, and with an increased velocity in the mains it would be possible to distribute it at such a price that it could compete with coal, say at 9d. or 1s. per 1,000 cubic feet of equivalent heat value. The benefit of this to the community would be enormous. There would be an entire elimination of smoke from the atmosphere and a consequent improvement in the sanitary condition of our towns and cities, the heating and ventilating arrangements would be under perfect and automatic control, and in every household the hard drudgery, done mostly by women, of carrying coal and ashes, lighting fires in the morning, and stoking them every hour of the day, would be entirely abolished, and at the same time all the valuable by-products, such as coal tar and sulphate of ammonia, which now poison the air we breathe, would be made available for industry and agriculture. The universal use of gas for heating and cooking is, therefore, one of the most pressing public needs.

We cannot hope to reduce the present quantity of fuel required for heating any given building to a certain temperature unless we first ascertain how the heat now used for this purpose is distributed. In testing the economy of engines and boilers, the great point is to give an exact account of the heat generated by the fuel, the heat utilized and the heat lost.

A large number of experiments have been made with domestic fires, but it does not appear that any heat balance sheet has been made, and although it is evident that great losses occur it is not clear from these experiments what becomes of the heat and why the heating effect is so small.

Some very careful and interesting experiments were carried out for The Coal Smoke Abatement Society by Mr. Alfred S. E. Ackermann, B.Sc. (England), A.M.I.C.E., and Dr. J. S. Owens, A.M.I.C.E. The best and most economical result was found with an open grate of the D.O. Boyd "Hygiastic" type which burned 3¾ lbs. of coal per hour when heating a room of about 4,000 cubic feet capacity. The total calorific value of the coal was 55,350 B.T.U., and this raised the temperature of the room to 59°F. when that of the outside air was 37°F., and that of the air entering the room from an adjoining passage was 41°F. A volume of 9,738 cubic feet of air per hour was drawn from the passage and went up the chimney with a velocity of 6.85 feet per sec., and at a temperature of 100°F. The heat used for warming this air during its passage through the room was 3,780 B.T.U., or 6.83 per cent. of the total heat evolved from the coal, and the heat used for heating the flue gases from 59°F. to 100°F. was 7,749 B.T.U., or 14.0 per cent. of the total heat. The remaining heat, 43,821 B.T.U., or 79.17 per cent. of the total, is given as radiated to the walls of the room, drying and heating them. It is evident that if the walls of a room were heated they would communicate their heat to the air of the room and that this would show itself by an increased temperature, and where this is not the case it is certain that the heat escapes through the walls and windows which are far more permeable to heat than is generally supposed.

Conductivity and Radiation.

The conductivity of a wall is for all moderate temperatures exactly proportional to the difference between the inside and outside temperatures and it is for brick walls approximately inversely proportional to the square root of the thickness of the wall.

To ascertain the radiation from an ordinary sitting-room, some approximate tests were made in a room with a floor area of 221 square feet and a height of 9 ft. 6 in., having a total capacity of 2,100 cubic feet. The room was heated with an "Artesse" anthracite stove burning day and night through the whole of last winter. The coal consumption varied from 16 lbs. to 25 lbs. for 24 hours, according to the temperature of the outside air. During the 16 hours per day, when the room was occupied, the temperature was kept as nearly as possible at 60°F., and during the night the fire was banked up with 4 to 5 lbs. of coal, the air supply was reduced and the temperature fell during the night to about 50°F.

During the coldest days of this year, when the outside temperature fell to 30°F., the coal-consumption during the day was about 1¼ lbs. of anthracite nuts per hour. Taking the thermal value of the coal at 15,000 B.T.U., the heat generated was 18,750 B.T.U. The windows were closed and the air supply for ventilation was taken from the corridor where the temperature was about 45°F., and through the leaks round the windows. The ventilation certainly did not come up to Sir Napier Shaw's standard and as nearly as could be estimated the change of air was 8,000 cubic feet per hour, and there were complaints of "stuffiness" when more than two persons occupied the room.

Heat Losses and Ill-Health.

The total quantity of anthracite coal used for the season was two tons, or an

average of about 20 lbs. per diem, and the efficiency of the stove was $\left(\frac{15{,}088\times100}{18{,}750}\right)=80.5\%$. The heat used for warming the air was only 14.5 per cent., all the rest of the heat being lost as far as this room was concerned, although the heat lost through the inside walls was useful as it raised the temperature of the corridor and adjoining rooms. Of the remaining heat 52.1 per cent. is dissipated into the outside air through the walls, floorboards and windows and the remaining 33.4 per cent. of the heat radiated into the room, escaped to the other parts of the house.

Dr. Owens' tests do not show the amount of heat radiated from an open fire either of coal or gas, and the author is not aware of any reliable radiation tests carried out with coal fires. With gas fires, however, a great many tests have been carried out by the two great London gas companies, and it seems certain that from an ordinary open gas-fire about 45 per cent. of the total heat of the gas will be radiated into the room, according to the latest bolometer tests.

The low percentage of heat radiated into a room from an open fire,—less than 20 per cent.—coupled with the high conductivity of the walls of an ordinary dwelling house, increases the cost of heating and also raises the death rate, and British tastes and habits must be successfully met by some apparatus capable of producing a pleasant and cheerful heat without wasting four-fifths of the heat uselessly.

Particular reference was made to the lack of proper heat insulation, compared with Continental and European practice, while mention was also made of a type of wood stove used in Petrograd, which while designed for wood, could be easily adapted for gas, were such fuel commercially available.

Insulation of Walls

The system of heat insulation to be adopted should be one that can be used for existing houses without any excessive expense. Slag-wool appears to the author to be almost an ideal substance for the purpose, as one inch of slag-wool is as good an insulator as a foot thickness of brickwork. It is, moreover, fire-proof, sound-proof, and vermin-proof, and is at the same time a fairly cheap material; the pre-war price was £4 10s. per ton, which contains 200 cubic feet, so that a layer 4½ inches thick would cover 530 square feet per ton and, therefore, cost about two pence per square foot of external wall surface, and if made in large quantities this price could, probably, be reduced. At the above price a suburban dwelling-house as described above could have the whole of its external walls, partition wall, ground floor and upper ceiling effectively insulated, equivalent to about 4 ft. 6 in. extra thickness of brickwork at a cost of about £35. For new houses the walls should be built with a hollow space filled with slag-wool during building. Slag-wool should also be placed between the joists of the floor and above the ceiling. For existing houses slabs of slag-wool may be attached to the inside of the walls. One in. slag-wool slabs will retain 60 per cent., two inches will retain at least 70 per cent., and four and half inches will retain over 80 per cent. of the heat now wasted.

As over 21.3 per cent. of the heat lost by conduction passes through the windows, it is of great importance that these should be more carefully fitted and that they should have double sashes.

A house fitted in this manner would not only be warm and comfortable in the winter, but also cool during the summer, for the same insulating material which prevents heat losses from within during the winter would prevent the entrance of heat from without during the summer. It would, further, be practically sound-proof and all the distressing noises, inseparable from great cities, and which so frequently disturb the rest of those that are unwell or indisposed, would be kept out of the house.

There would also be a great reduction in the domestic work, not only would the lighting and stoking of fires be abolished, but dust would be prevented from entering and a great deal less dusting, washing and house-cleaning would be required. If the heat losses are reduced 80 per cent., the fuel used for heating the whole house to a comfortable temperature would actually be less than the fuel now used for heating one or two rooms in the very imperfect manner it is done at present.

RECOVERY OF LUBRICATING OILS

LARGE quantities of oil are used in all machine installations, for lubricating purposes, and though the amount actually required to effect efficient lubricating is relatively small in each case, considerable excess is, for one reason or another, generally employed. For the sake of cleanliness, catch pans or grooves are provided to receive all oil working through bearings, so that the excess oil, mixed with dust and dirt, and usually "worn" to a more or less insignificant extent, is available for re-use, providing it be first cleansed. Machines for this purpose are to be had, but some of these require much attention in order to maintain satisfactory results, and cannot in any case be applied to thick cylinder oils and similar lubricants. The demand for a simple means of cleansing oils rapidly and economically is perhaps best met by centrifugal separators.

With more or less unimportant distinctions between individual makes, these machines comprise a conical whirling receptacle keyed on to a shaft and rotated at high speed within a stationary cast-iron drum. Oil to be cleansed is placed in a container within the whirling frame, and the latter is set in motion. Centrifugal force drives the oil up the smooth walls of the container to the rim, and hurls it thence through a fine brass gauze screen, which removes light foreign material carried up with the oil; heavy impurities remain at the bottom of the rotating vessel. In large installations it is preferable to employ separate machines to remove heavy particles from oil, and to clarify the latter completely. Purified oil may be conveniently compared with new oil by smearing a drop of each side by side on a sheet of clean paper. When the latter is held to the light, any suspended particles of muddiness in the separated oil will be easily detected.

BOILER INSPECTION AT MONTREAL

ALTHOUGH his annual report is a year behind, boiler inspector E. O. Champagne is once more able to inform the public that for the year 1915, no boiler explosions occurred in Montreal. This long immunity from serious boiler accidents has been a feature of Mr. Champagne's reports for many years, and in that connection a letter of congratulations is quoted from the Travellers' Indemnity Company of Hartford. The following is the record for steam boiler inspection for 1915:

Visits of inspection	3,112
Internal and external examinations	1,889
Hydraulic tests	1,621
Hydrostatic tests	606
Imperfect boilers	203
Boilers condemned	4
New and second-hand boilers erected	77
New boilers (included in this number)	65
Notices of inspection issued and received	922

The licenses issued to engineers and others after due examination to take charge of steam boilers was 2,255. Those who failed to pass examinations numbered 127.

Visits made in connection with new devices for smoke abatement were 767

CUBAN DEMAND FOR GASOLINE MOTORS

UNITED STATES CONSUL R. M. BARTLEMAN, Cienfuegos, Cuba, in a report to his Government published in the Commerce Reports, says that a very fair demand for gasoline motors exists in the Cienfuegos district, but on account of the excessive advance in the price of gasoline there is a tendency to turn to the crude-oil engine.

The following quotations have been obtained: 1¾ horse-power, $78; 1½ horse power, $55; 4¼ horse-power, $95; 4 horse-power, $180; 6 horse-power, $185, $215 and $375; 8 horse-power, $285.

Dealers also offer a complete plant for lighting and industrial purposes (the heating feature being superfluous for this climate), consisting of engine, motor and storage battery, with a capacity for 10 lights, costing at factory $150, placed on market here at $240. Others, of 20-light capacity, with a factory cost of $200, sell here at $320.

Electricity and Hydraulics

COMMUTATOR TROUBLES

Vulcan Staff Article.

AS commutator and brushgear are the most frequent sources of trouble in direct-current motors, a few remarks on the care required to maintain these details in order may be of service to operators and attendants generally. The commutator is, perhaps, the most sensitive detail and deserves more attention than it usually receives, though, given proper design, it should not require more attention than is called for with ordinary wear and tear. The secret of success of satisfactory running depends on three important points:—

1—Correct brush position relative to field poles of machine.

2—Correct spacing of the brushes round the commutator.

3—Good contact between commutator and brushes.

Correct Brush Position

Correct brush position is a condition that can best be arrived at by trial, but under normal conditions the heel of the brush should be very nearly opposite the centre of the corresponding shunt field coil. In the case of a multi-polar machine, the number of commutator sections between each pair of adjacent brush arms should be equal, and, once set, this condition will remain, except after such times as the machine is dismantled for cleaning or repairs, when it sometimes happens that the spindle carrying the brush boxes receives a twist sufficient to displace the brush on the commutator surface as much as the width of one or more bars. Sparking trouble may, however, remain even if correct conditions are complied with, should brushes and commutator fail in making good contact.

The chief cause of this is known as "high mica," and is due to the copper sections of the commutator being softer than the intervening mica sections, with the result that the copper burns or wears away at a greater rate and leaves the mica projecting above the copper. This is most liable to occur in commutators having a large number of thin bars, and where, therefore, the percentage of mica is high as compared to the copper. The amount the mica projects is, of course, only small, and can best be detected by drawing the finger nail along the radial surface of the commutator. This small projection, however, is sufficient to cause the brushes to lift and spark as the machine revolves. If not attended to at once, this sparking may eventually become so bad that the machine is unsafe to run, or may not even run at all. Any polishing or grinding that can usually be applied has the tendency to clean up the copper, but still allow the mica to be upstanding, and it is necessary to recess each mica section to a depth of about 1-32 in. to 1-16 in. below the surface of copper.

With recessed mica the brushes are able to maintain uninterrupted contact and eliminate the burning and sparking, thus increasing the life of the commutator and the brushes, reducing the temperature and generally improving the operation of the machine. There is one drawback, however, to recessed micas: carbon and other dust can accumulate in the cavities thus made, and such material being more or less a conductor, causes shorting of adjacent copper bars, with consequent burning out of coils. If, however, the slots do not exceed the depths given, and the commutator is periodically blown free from dust and no oil is allowed to get on to the commutator, there should be no trouble.

Breakdown Experience

In connection with this subject of commutator troubles, a breakdown which recently came under the notice of the Vulcan Co. electrical surveyors is instructive. A large d.c. generator recently broke down, due to a "flash over" at the brushes, and two large holes were burnt through the mica end ring and into the cast iron clamping ring, and three of the commutator bars had about 2 in. fused off the ends. A few days afterwards, notification was made of a breakdown to another d.c. generator, some of the armature coils having earthed. The inspector sent to examine it reported that shortly after the first accident the engineer-in-charge noticed smoke issuing from the armature of the second machine, which was standing at the time, and on investigation found that some dirt in one of the air ducts between the windings was on fire. As he could not extinguish it, he injected some water, which undoubtedly damaged the insulation and resulted in the earthing of the coils. It was afterwards established that a piece of molten metal from the fused end ring of the first-mentioned generator had been thrown off and dropped down the air duct of the standing machine, setting fire to the dust in the air duct. Pieces of molten metal also fell on the main switchboard about 30 ft. away.

HYDRAULIC RESOURCES AND INDUSTRY

IN estimating the value of Canada's hydraulic resources and their importance with reference to future industrial development, the extent to which electro-chemical processes have entered into some phases, at least, of nearly every branch of our industrial life is not generally appreciated.

A small beginning in electro-plating, two generations ago, has developed until the great bulk of the copper output of the world is electrolytically refined. The electrolysis of common salt is the basis of the electrolytic alkali industry, the products of which are caustic soda, metallic sodium, chlorates, and hypochlorites. The electric furnace has created a host of new industries, producing chiefly abrasives, graphite, silicon, ferro-alloys, refined steel, phosphorus and calcium carbide. It has also been tested experimentally as a competitor of the combustion furnace in the metallurgy of many metals.

Used as an electrolytic furnace, we have the very important application to the production of aluminum. The industrial use of electric discharges through gases is still in its infancy, but we have ozone and nitric acid among the products, the former used for sterilization, and the latter as a basis for fertilizers and explosives.

Every one of these industries consumes large quantities of energy. Whereas the refining of lead requires only 120 k.w.h. per ton, we have consumptions as high as 4,000 k.w.h. per ton for other metals. The aluminum furnace requires 25,000 k.w.h. per ton of product.

The electro chemical industries have grown to be of great value to countries which possess good opportunities in water power resources, as they have a fundamental interest in the development of cheap power.

LUBRICATION

By R. W. Reay.

THE question of lubricants and the method of their application require more careful consideration now than was the case a few years ago owing to the rapid development of the internal combustion engine and the more prevalent use of high temperatures and pressures in steam engines. The present-day aim is to secure higher efficiency and greater reliability. To this end lubrication be-

comes a very important factor. The efficiency of an engine is greatly impaired by the use of an unsuitable low grade lubricant.

In the selection of an oil, one should be guided more by the results derived from its use than by its gallon cost. It is necessary when selecting an oil to know the actual conditions under which it is expected to work. The question must be studied for each particular type of engine, and thought must be given to tthe type of lubricating appliance in use, because wrong application or overfeeding of oil is often the cause of serious trouble. The main function of a lubricating oil is to create a complete film between the rubbing surfaces, thus preventing metallic contact. The two chief properties in a lubricating oil are:—The quality of oiliness "body," and the viscosity.

Speaking generally, the greater the load upon a bearing the more body the oil must have to carry the burden, while with regard to viscosity the oil possessing the lowest viscosity in conjunction with sufficient oiliness to form a complete oil film will give the least co-efficient of friction. It is, of course, necessary that the oil should maintain these properties when in the form of a thin film in which state it exists between the rubbing surfaces, and it should neither evaporate nor become gummy during use.

Steam Cylinder Lubrication

When selecting an oil for steam cylinders and valves, two important factors to be considered are the type of engine, whether vertical or horizontal, and the steam temperature. The oil that would suit and give the best satisfaction on a high speed vertical engine would not be the most suitable for the slow running horizontal, owing to the weight of the piston having to be carried by the oil to prevent metallic contact with the lower side of the cylinder.

Where superheated steam is employed, the oil is not washed out of the cylinder by the condensation of steam, but remains for a long time exposed to the high temperature, so that the best quality cylinder oil applied in a proper manner should be used. If an unsuitable oil is used, a carbon or sticky deposit will result.

Marine Engine Lubrication

The syphon system is commonly used for the external lubrication of marine engines, though in some cases the method of hand oiling is still adopted. The great drawback of the latter is the intermittent supply. The bearings get more oil than is necessary at the moment and are almost dry before it is again applied. With the syphon system there is a uniform flow on the bearings giving even lubrication with little or no waste. The oil most suitable for marine engines is one that will emulsify with water. There is always a certain amount of condensation taking place, due to leakages from piston and valve rods, and, therefore, the lubricating properties of such an oil are less effective than oils purely mineral in character.

A firm that had been using low-priced oils decided to try if they could obtain more economical results with those of high grade. The engine is a 500-h.p. vertical steam unit, driving a large factory. Before changing the oil they ascertained the number of free revolutions with all the belts through the factory on loose pulleys. This was done by starting the engine at lunch hour, and, on reaching the normal speed, the throttle valve was shut and the number of free revolutions made by the engine recorded. An average of three days was taken and found to be 47 free revolutions.

The new oil was then put on, and after eight weeks' running an average of three days was again taken. This time 57 free revolutions were obtained, showing an increase of 10 revolutions. The conditions in each case were exactly the same, the speed of the engine being indicated by a tachometer showing exactly the same number of revolutions on each occasion at the point of closing the valve, and despite the fact that the high grade oil cost more, the actual running cost worked out lower, as there was less being used. A test of this sort can often be easily carried out, and being absolutely reliable is a good object lesson.

A good deal of trouble is often caused by overfeeding of cylinder oil. One case of this came before my notice recently. The engine was a 50 h.p. triple expansion horizontal steam unit. On the cylinders being opened, they were found to contain an abnormal amount of carbon deposit. When the engine was again started, the feeds were reduced to exactly one-fifth the previous amount. After running some time, the cylinders were again examined and found to be in splendid condition with no trace of carbonisation.

Diesel Engines

In the early days of the Diesel engine a considerable amountof trouble was experienced, due to breakdowns. It was found in many cases the trouble was caused by the piston "seizing" in the cylinders. The lubricant used was not suitable to the intense heat to which it was subjected. The pistons are lubricated by a mechanical lubricator, one pipe being led from the lubricator to each cylinder and a number of branches, usually 4 or 8, taken from this and led through the water jacket at various positions round the cylinder. A better method would be to have a separate pump for each entrance, two feeds (front and back), for pistons up to 20-in. diameter, as the greater part of the feed is liable to go in at the point nearest the lubricator and the point furthest away would get little or no oil. The proper place to inject the oil is between the first and second rings when the piston is at the bottom of the stroke. This can only be done by employing a mechanically-operated lubricator of a special design.

The majority of Diesel engines are open type. The gudgeon pins are lubricated by a mechanically-operated lubricator through the cylinder wall; a scraper attached to the gudgeon pin scraping off oil from the cylinder wall and guiding it into the gudgeon pin bearing surfaces. Main bearings are nearly always ring oiled and crank pins banjo oiled. The force feed circulation system is frequently used for bearing lubrication. Splash guards are sometimes fitted in the crank chamber having openings for the connecting rods. This prevents the oil leaving the crank webs from reaching the cylinder walls.

An oil must be selected to suit the conditions, and be of the best quality obtainable since the oil in the crank chamber is nearly always affected by the admixture of liquid fuel. Any fuel oil that has not been properly burned mixes with the oil on the cylinder walls and gradually works past the piston rings into the crank chamber, the result being that the oil becomes contaminated and its lubricating properties impaired. The carbonised matter coming down from the piston makes the oil dark in colour.

With the forced feed circulation system, there is a great likelihood of the oil, which is constantly being splashed to the cylinder walls passing the piston rings and getting to the top of the piston, where it will be burned and leave a carbon deposit. This is sometimes provided against by having the rings pegged, so that, after working a little while, they adapt themselves to the shape of the cylinder, this preventing the oil from passing, and the explosion gases from blowing past into the crank chamber. When the piston rings are not pegged, a very heavy-bodied oil is used to seal them. This is not an advisable practice. The heavier the oil the more power is lost through friction, and a greater carbon deposit formed on the piston rings. If too thin an oil is used it will pass to the top of the piston in large quantities, which means heavy consumption and excessive formation of carbon. Oils properly selected and manufactured have considerably longer life in the circulation system than ordinary oils improperly manufactured or not selected with the same care.

The temperature inside the crank case is usually high in enclosed engines owing to the fact that the pistons get less cooling from the air and the hot gases occasionally escape into the crank chamber. When using a high class oil, the friction is considerably reduced, the crank case temperature is lower, less power is needed to overcome friction, and less wear and tear of the working parts will result. From a paper read before the Institute of Marine Engineers.

Use of oil in generating power is much more effective when applied to internal-combustion engines than when consumed as fuel under boilers. In the one case a barrel of oil gives power for crushing 14 to 15 tons of ore; in the other only for 1¾ to 2 tons.

REFRIGERATION DEPARTMENT

FLOODED SYSTEM OF REFRIGERATION

By S. S. Wyly.

ONE of the recent developments in the field of mechanical refrigeration is the application of what is commonly termed the flooded system. It is not, as may at first be supposed, a distinct system of refrigeration; instead it is an improvement in that part of the ordinary system in which the freezing or refrigerating effect is produced. In the ammonia compression system, as applied to the cooling of brine for ice-making or indirect refrigeration, the liquid ammonia from the condenser is collected in a receiver, from which it is led to the expansion valves and allowed to pass through into the pipe coils in the brine tank. In passing through the expansion valves from the high pressure side to the low pressure side, the liquid ammonia is converted into gas, the heat for this evaporation being taken up from the brine surrounding the coils. Thus, the evaporating coils are filled with gaseous ammonia at a low temperature and pressure.

Evaporating Coils Content

The flooded system differs from the foregoing in that the evaporating coils are flooded with liquid ammonia; that is, the interior of the coils, instead of being filled with ammonia gas, are kept nearly or quite full of ammonia liquid. The object of this is to obtain an increased efficiency by reason of a more rapid transfer of heat from the brine to the ammonia. The increased rate at which heat is transmitted is due to the fact that both the inside and the outside surfaces of the pipe coils are wetted by contact with liquid. One of the proved facts regarding heat transmission is that a greater quantity of heat can be transmitted per square foot through metal plates from one liquid to another than from a liquid to a gas or from a gas to a gas, other conditions being the same in all cases.

Because of the flooding of the expansion coils, each square foot of pipe surface is able to transmit from 50 to 75 per cent. more heat per degree difference of temperature, than when the coils are filled with dry gas and the heat is transmitted from a liquid to a gas. Of course, the more rapid the heat transfer, the greater the refrigerating effect produced in a given time, and the higher the efficiency of the system as a whole.

*From a paper read before the Kentucky Ice Manufacturers' Convention.

Since the coils are practically filled with liquid ammonia, the evaporation required to maintain the brine at the desired temperature produces a mixture of gas and liquid in the pipes. Consequently, in the suction line to the compressor there must be a separator or trap by which the liquid and the gas will be separated, so that only dry gas will be drawn into the compressor cylinder; and the liquid thus separated must be returned to the coils.

The Accumulator Device

The device by which the gas and the liquid are separated is called the accumulator. The suction line to the compressor leads from the top of the accumulator, and the line from the bottom leads back to the liquid header, a check valve being inserted in this line to insure correct operation. The gas is drawn from the suction header above the evaporating coils through a pipe into the top of the accumulator, on its way to the compressor. In the accumulator, which is a vertical cylindrical chamber of considerable length, the liquid ammonia falls to the bottom and from there flows by gravity through the pipe back to the expansion coils. Since the interior of the accumulator is subjected to the suction pressure there is a tendency to cause a flow back through the pipe from the liquid header. To prevent any such flow, a check valve is placed in this line which will permit the liquid ammonia to pass to the expension coils, but will not permit it to return by the same pipe. The result is that the flow is confined to the one desired direction.

In the process of cooling the brine surrounding the coils, the heat transmitted to the ammonia causes some of it to evaporate, so that the coils contain a small proportion of gas. If it were not for the check valve, the gas in the lowest coils would be drawn back through the pipe, from accumulator to coils. The level of the liquid in the accumulator is shown at all times by an indicator attached to the side of the accumulator. The feed through the expansion valve need be only sufficient to maintain the proper temperature in the brine tank.

This describes the flooded system as applied to the ice-making system in which there are coils arranged in sections. Each section is a divide between each row of cans. These coils are built up about eight pipes high and of such length and number of coils as is necessary to contain about 300 lineal feet of 1¼ in. pipe per ton of ice made in a day of 24 hours, all of this to be arranged into a tank of such size as will accommodate coils and ice cans, the coils and cans being submerged in brine of such density as not to freeze.

Shell and Tube Brine Cooler Type

There is one other flooded system that has been in use for the last few years, which is known as the shell and tube brine cooler, so arranged at one end of the ice-making tank that the brine can be drawn or forced through the tubes to the brine cooler. In this process, the brine is cooled to the desired temperature and then sent to the ice tank, which is arranged without coils—nothing but the cans filled with water to be frozen. The tank is so arranged with partitions that the brine passes very rapidly through the tank and back to the cooler where it is recooled, and thence through the same operation again.

With the shell and tube brine cooler you will note there was no accumulator mentioned. This is due to the fact that there are no coils connected, the brine cooler being simply a shell filled with 2-inch tubes and placed as close together as is consistent with good designing, for strength. The liquid anhydrous ammonia is fed into the shell at a rate to guarantee the proper height of liquid to be carried in the cooler, which is about two-thirds full, the cooler being in a horizontal position. As the heat from the brine is transferred through the tube to the liquid ammonia, the liquid is evaporated into dry gas, just the same as steam is evaporated from a horizontal return tubular boiler. The evaporated gas passes off at the top of the cooler to suction line of the compressor or the return line of the absorption machine. The amount of gas that is thrown off at this cooler determines the size of the machine, whether it be a compression or an absorption machine.

The Economy Feature

It will be noted that no mention has been made of economy, which is the most important item to be considered when entering into a new method. The very first thing that is considered when contemplating an improvement of any kind, is, how much is the investment? How long will it take to pay out, and how much is it going to increase our net earnings? I don't believe I have ever found an instance of a material saving having been made. If we make a new installation, the cost of the accumulator and extra charge for ammonia will about offset the amount of cooling surface that has been saved by the rapid transmission of heat through a smaller

number of square feet of cooling surface; and as to making a change, it would be useless to go to the expense of equipping an existing dry gas system with one that will increase the output of the freezing system only.

Bear in mind, I am basing this statement on the fact that you have a machine that is capable of handling a a given number of heat units every 24 hours, and by adding a new system that produces twenty or twenty-five per cent. heat units per twenty-four hours, the machine with its respective parts will have to be increased (or, if with a compression machine the speed will have to be increased), using steam at the same ratio as in the former case. Quoting from a previous article of mine on this subject, "three hundred feet of 1¼-inch pipe is used per ton of ice in the ice tank, when with the flooded system only half or two-thirds this much is needed," and just recently I find published in one of our popular journals an article describing a most modern and up-to-date ice plant where, even with the flooded system, they are still using 14.3 cans per ton and 300 feet of 1¼-inch pipe per ton, and to-day, under the dry gas system, at one of our plants we have five hundred and thirteen 300-pound cans with 300 feet of 1¼-inch pipe per ton, pulling 240 blocks of 300 pounds of ice each twenty-four hours, which is 14.1 cans per ton.

Question of Adoption

It is not the object of this paper to take issue against the flooded system, for, from foregoing part of paper, it is a foregone conclusion that the flooded system will transfer heat more rapidly than the dry gas. It will be noted that I have put the question as if it is applied to a specific case; in other words, to determine whether it is necessary to change present equipment to the flooded system, which is practically using the same material as in the old-fashioned dry gas system.

Reference has been made to a tank with 513 cans producing 36 tons of ice, which is equivalent to 14.3 cans per ton. We also have another plant where the circulation is better and are producing 72 tons of ice per day on this tank of 960 cans, which is equivalent to 13.5 cans per ton. This is about as good a record as can be produced on ice-making tanks, for if you use a smaller number of cans per ton, it will be necessary to carry such extremely low temperatures as to result in cracked ice.

GEAR WHEEL PRACTICE

IN the old mill-wrighting days, says The Power User, whenever it was desired to transmit power from an engine to various pieces of machinery, advantage was taken of the peculiar conveniences that gearing offers, much more than is the case at the present day, notwithstanding the great improvements that have been made in late years in the production of toothed gears. Some fifteen or twenty years ago the writer had to scheme out a drive for a factory in which one place, and one place only was suitable for placing the steam engine, the installation of which he was responsible for. It was in a recess cut out, cave fashion, in the side of a chalk cliff at right angles to one long room furnished with various machines. In a second room, at an obtuse angle with the first, other machines were placed, and, being brought up to belt drives almost exclusively, attempts were made to solve the problem of driving the two inclined shafts by belting from the engine.

All sorts of schemes were considered, but all difficulties were solved by an engineering colleague in the simplest manner. Careful measurements enabled the exact angle to be determined, and a pair of bevel wheels were cast to gear at that angle and the puzzle was solved. It was a lesson that has never since been forgotten. Yet one rarely finds that any other than parallel and right angle drives are arranged for to-day, although, in many instances of irregularly shaped structures, it would often be a convenience if bevel wheel drives arranged for the required angle were adopted. Is many cases it would be possible to arrange the machinery to much better advantage and thus to obviate waste space.

This experience was called to mind by listening recently to an informal discussion by the members of the Junior Isstitution of Engineers in London upon the subject of gearing. The speaker who opened the subject was an expert on gears and gave some interesting information of general interest. He spoke of the various types of gearing used to-day for different purposes, of their characteristics and their limitations, and advised his hearers to "leave it to the expert." It was a little difficult to accept this advice, however, for he instanced shortly afterwards, as an example of unsatisfactory operation, a case in which a firm specialising in worm reduction gears failed to do what was required, as the circumstances were such that double helical gears would have been much more suitable. That is the worst of relying upon gear makers' advice. They are so apt to quote for what they are, for the nonce, specializing upon, to promise for their products of the moment rather more than can be or ought to be claimed.

For reasons which will be obvious to our readers, it is undesirable to make comparisons between different specialities in commercial competition, but it may be said that in the writer's own experience the advice of power gearing "experts" proved to be somewhat unfortunate and expensive. Making a spe-fortunate and expensive. Making a spe-a pair of wheels was supplied by a certain firm in connection with an electric motor, the pinion being keyed to the motor shaft, and the spur wheel on the main shaft transmitting the power to several machines. When set to work the gears worked very noisily and soon showed signs of undue wear. The writer's opinion was sought, and it was very evident that the wheels were endeavouring to preserve one fixed relative position of contact with engaging teeth, while the "floating" of the motor armature was pulling the teeth out of this natural line of contact.

The advice was given to key the pinion in such a position on the motor spindle that, when at work, the magnetic centre of the armature would be gained and would keep the pinion teeth in correct line of contact with the wheel. This however, was easier said than done, for variation of output could not be obviated, and the armature continued to float in consequence and did not keep to a definite magnetic centre. This defect is a well recognised one in any form of tooth gear which necessitates strict alignment of engaging wheels, and to get over such difficulties it is often specified that flexible couplings be provided on either side of the gears.

In a gas or oil engine drive, for example, when it is requisite for an engine speed of 250 to be increased by gearing to actuate a centrifugal pump spindle running at 900, then it is advisable to fit a flexible coupling on the engine shaft and another on the pump shaft; and, more than this, to adopt adequately proportioned bearings to the two spindles of the gears so as to firmly support them on both sides; to provide for adequate lubrication of the four bearings, and to project a stream of oil, preferably under pressure, at the point of tooth engagement to minimize wear, and particularly so when the pitch velocity is fairly high.

An Interesting Study

Gear wheel practice is a very interesting study to-day and it is a subject which should not be "left to the expert" with blind confidence. Factory engineers have bought much experience at too great cost by so doing, and it behoves them to at least know sufficient about the subject as will enable them to discriminate the relative merits of commercially competing tooth formations. It may be true that a worm drive is comparatively inefficient when compared with others, but there are many cases where a worm drive is the only practicable one, and therefore its relative inefficiency is of no consideration.

In the discussion to which allusion has already been made, the "hunting" tooth was referred to. It seemed that the very advantage of the hunting tooth was to-day considered a disadvantage by the expert who suggested—apparently seriously—that if this hunting tooth was a shade tighter than the others, then it would wear unduly every tooth in the engaging wheel, whereas if it were omitted all teeth would be worn evenly. He seemed somewhat surprised when it was suggested to him that he had raised a bogey just for the sake of knocking it down, seeing that there was no reason is the world why the hunting tooth should be any different to the others in a gear wheel. As a matter of fact it is to ensure regular wear of all teeth that the one extra or "hunting" tooth is provided.

FUTURE ASPECTS OF SKILLED LABOR.

ONE of the principal handicaps which manufacturers are likely to encounter in this country, in the generally expected struggle for after-war trade, will be the obtaining of a supply of suitably trained labor. Observers, both in Britain and America are noting closely the present tendencies of the situation, and where possible are exerting personal influence to the end that the employee's interests in obtaining a proper training are too closely identified with the employer's to permit the latter to ignore the facts of the case indefinitely.

A few mechanics are born, some are trained, but a large proportion are the creatures of circumstances, who started in a machine shop as boys glad to get rid of school studies and brain work of any description. Perhaps the machine shop was the only local opportunity; had it been a packing-house or a cheese factory, they would have started there for just the same reasons. Such youths seldom remain long enough or work seriously enough to imbibe any ideas of the trade's requirements; they may ultimately manage to read a micrometer and yet be unable to work a problem in decimal fractions, and no one cares, at the time.

These conditions have been common in the past—most of our readers are probably able to recall such individuals and occurrences—and all of them have doubtless agreed that when all was said and done, the employers have themselves to blame, because they don't want to spend their own time or money training help for the ultimate benefit of other firms, and when the majority of employers view the situation thus, no remedy seems applicable.

Nothing but a return to ordinary commercial work will bring about the previous state of affairs. The repetitive feature of shell production will not be present, and the efforts of this country to build up a foreign trade will involve for some time a variety of manufacture, throughout the country generally, and in many shops in particular, which will create a real demand for the all-round machinist, and it is in their efforts to anticipate this demand that manufacturers, who are laying plans for the future, have opportunity for displaying a degree of prescience, indicative of their ability to play a larger part in the future upbuilding of our industries.

HELP TO WIN THE WAR

THOSE who cannot go to the Front can help in a most practical way by saving their money and placing it at the disposal of the Government to assist in financing the war. The new War Savings Certificates which have been created by the Government to encourage thrift and economy, and to give everyone an opportunity to assist in financing our war expenditure, are now on sale at every bank and money order post office in Canada. The $25 certificate sells for $21.50, the $50 for $43, and the $100 for $86. As an investment, these certificates offer many attractive features—chief of which are the absolute security and the excellent interest return. For every $21.50 lent to the Government now, $25 will be returned at the end of three years.

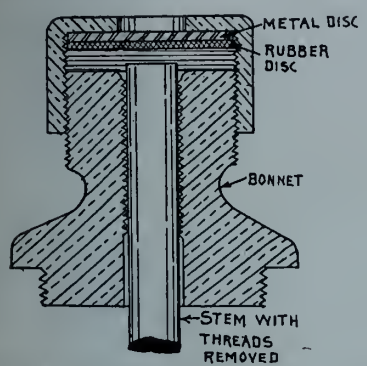
There are two other features which are especially interesting to small investors. First, the certificates may be surrendered at any time, if the buyer should need his money; and second, each certificate is registered at Ottawa in the buyer's name and, if lost or stolen, is, therefore, valueless to anyone else. Notwithstanding their excellence from an investment standpoint, the certificates should appeal strongly to our people, because they offer to those who must needs remain at home a splendid opportunity for a most important patriotic service.

The Operators' Point of View

HOME-MADE CHECK VALVE FOR BOILER TEST PUMPS

By J. E. McCormack.

EXPERIMENTING with home-made force pumps for boiler test purposes, the writer found it convenient to utilize a couple of old globe valves from the scrap, which



HOME-MADE CHECK VALVE FOR FORCE PUMP.

were quite capable of withstanding the occasional pressure demands without break or leakage, even though not quite suited for continuous operation. Many globe valves, especially those with renewable faces, are ultimately scrapped through failure of threads, either on the valve stem or for the stuffing nut to screw on to. The failure of either of these renders the valve useless for its original purpose, but with a small amount of doctoring it will serve very well as an extemporized check valve.

The first thing to do is to grind the threads off the valve stem so that it will slide freely back and forth in the bonnet without sticking. Now remove the stuffing nut, assemble the parts together and mark the valve stem level with the top of the bonnet, cutting it slightly shorter than the mark, according to the amount of lift desired. A metal disc is now made a fairly close fit for the inside of the stuffing nut, a rubber disc being also made to fit in the same place. The sketch shows the parts assembled, but not tightened down into position. When the stuffing nut is screwed home, the rubber disc makes a tight joint with the top of the bonnet and prevents leakage from the valve stem, the lift of which may be increased at any time by cutting more off the end. Should the threads on the bonnet be badly worn, the top of the bonnet may be cut down some so that the stuffing nut will get a hold of the unworn threads. Should this fail there is frequently enough metal to allow of a standard pipe thread being cut, to accommodate a pipe cap in place of the stuffing nut.

These valves, of course, are not suited for continuous operation, but, when tried out with a force pump on boiler test work at 100 lbs. pressure, operated quite as satisfactorily as entirely new check valves.

TWO USEFUL KINKS

By John Thorn.

TAKE an ordinary monkey wrench, drill two holes in the jaws for ¼ in. steel pins, cut a slot in the upper jaw to admit an ordinary cutter wheel, and another slot ⅜ inches wide in the olwer jaw for a roller; a cutter wheel can be used instead of the roller if desired. This converts the wrench into a passable iron pipe cutter, Fig. 1. By removing the pins and cutters, the wrench can be used as usual.

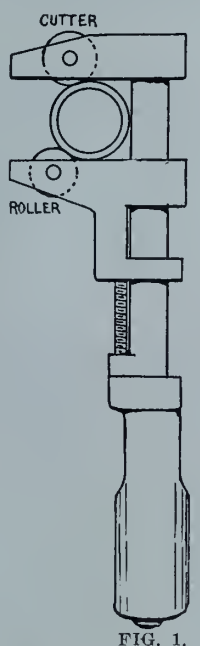


FIG. 1.

Another useful idea is shown in Fig. 2, this being a pump for testing pressure gauges. The body is a piece of 1½ in. heavy brass pipe, threaded at each end with standard pipe threads; a light cap is put on one end, while on the other end is threaded a heavy cast iron cap drilled in the centre and tapped for an ordinary ⅝ in. bolt. A long stem, with a T-handle, is threaded nearly the whole length as shown. This stem is a piece of ⅝ in. iron or brass rod which, with two iron washers, nuts and a cup leather, forms a plunger. A test gauge and a gauge to be tested are attached to the elbows at A and B.

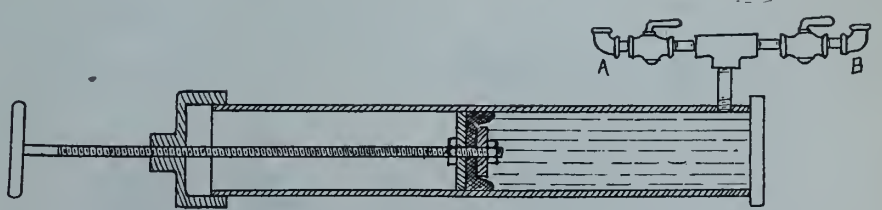

FIG. 2.

Before testing or attaching the gauges, place the lower elbow in a dish of water and leave the pit cock at B open and the one at A closed. Screw the plunger down as far as it will go, and then turn it back to the upper position with the elbow under the surface of the water; this will fill the pumps with water. Attach the gauges, open the pet cock and turn up on the T-handle, when a pressure of several hundred pounds can be secured with ease. The reason for using brass tube is because the inner surface of brass tube is usually much smoother than iron.

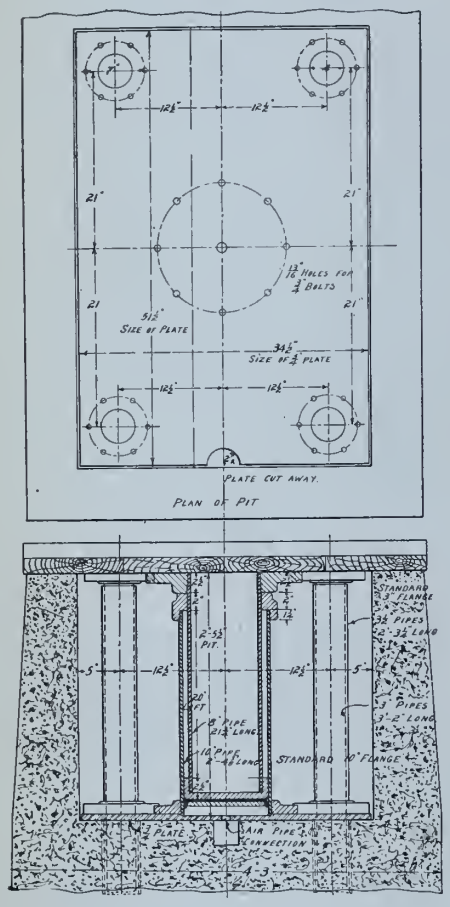
When a gauge is either weak or strong, all that is usually necessary to put it right is to remove the pointer and dial, oil the inner mechanism with a little coal oil, using a tooth brush (be sure none of the bristles are left behind), and replacing the dial and pointer so that it will just rest against the pin. Of course, if any cog or sector teeth are broken, or the spring tube is leaking, that is another story; but nine times out of ten all that is wrong is the pointer. The writer remembers once finding five pressure gauges in a plant, all of which had been discarded as useless, and in less than an hour had tested all of them, moved the pointers, and after testing again, they were absolutely correct with the test gauge. Gauges should not be placed where they will become hot, and steam should never be allowed to enter the spring, either of which conditions will ultimately destroy its usefulness.

ELEVATING PLATFORM

By E. T. S.

ALMOST every manufacturing plant has a lifting proposition somewhere or other, in which the lifting platform style would be the ideal thing. The method outlined in the following may be very simply arranged in plants where compressed air is employed, for the rea-

son that practically the whole outfit is made from standard pipe fittings. The elevating platform, shown in diagram, shows the simplest form of this arrangement with a single piston. We have in use at our plant several of these elevators which have a second piston, that is to say, the telescopic pipes comprise three pipes instead of two as shown. The base of the outer pipe is simply a pipe flange which is bolted to the base plate covering bottom of pit; a hole in the centre provides the air inlet. The top end of this outer pipe is threaded on to a reducer coupling bored out to suit size of inside pipe. The bottom end of the inside pipe is fitted as a piston with a single leather packing ring, and at the top end is a standard flange to which is attached the elevating platform. If the platform is large, it is necessary to provide guides in order to steady ascent



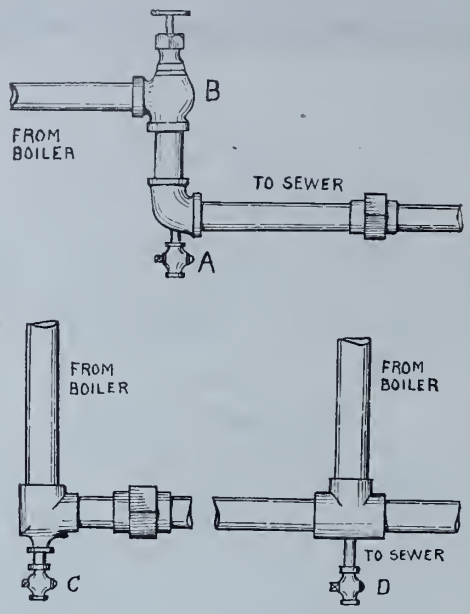
ELEVATING PLATFORM DETAIL.

and descent. For these guides we have four pipes 3½ inches diameter, into which slide four pipes 3 inches diameter. The larger pipes are fitted with standard flanges, and bolted to bottom plate, while the smaller pipes are similarly fitted and bolted to underside of platform. The whole is built up in a concrete pit having the platform ground level, so that trucks can be run on easily, and is controlled by a standard ¾ inches four-way valve. It is a low-priced elevator, gives good service, and hard to put out of service.

DETECTING LEAKY BLOW-OFF COCKS

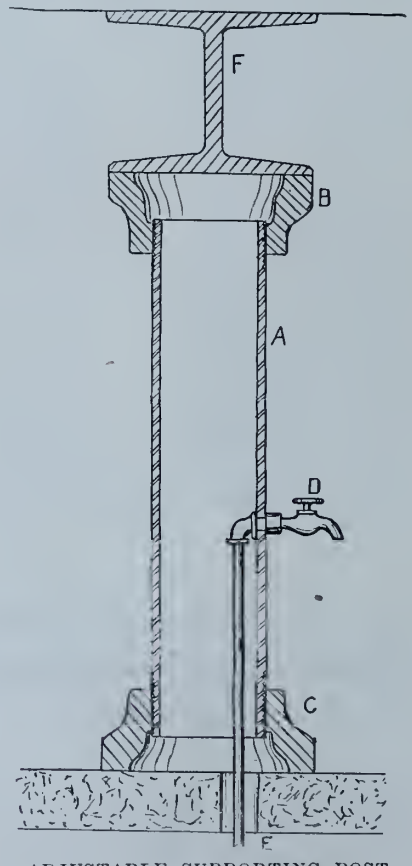
By E. N. Port.

THE majority of blow-off pipes which are connected to sewers or outside tanks, have no openings to show if the blow-off valves are leaking. Some of them



ARRANGEMENT OF BLOW-OFF PIPES FOR DETECTION OF LEAKY COCKS.

have tees instead of elbows, attached to the pipe, on the sewer side of the valve, with a plug screwed into one opening of the tee. Perhaps this plug may be removed "once in a blue moon" to see if



ADJUSTABLE SUPPORTING POST.

there is any leak, and perhaps not. A simple but good idea is to attach a small plug cock as shown at A. If two or more boilers are in a battery, different cocks can be attached, as at C and D.

It is no trouble to open one of these small cocks, and by doing so it can be seen instantly if the blow-off cock is leaking. A flange or union should always be placed near a blow-off cock so that the valve can be removed for repairs at any time without taking out a long stretch of pipe.

ADJUSTABLE SUPPORTING POST

By L. U. N.

AN adjustable pipe post is shown in the accompanying sketch, made from 6-inch steam pipe threaded right hand on one end and left hand on the other. Two heavy cast iron flanges are shown on the ends at B and C. This post can be placed under a ceiling or I beam already in place and by using pipe tongs to unscrew the pipe a few turns, a tight bearing can be made, the flanges being held with chain tongs while the pipe is being unscrewed.

In the post shown, a hole has been made in the concrete floor at E large enough to allow the elbow on the water pipe to pass through, a hole being drilled in the post to allow a nipple to pass through freely, and a drinking tap connected as shown at D.

REVENUE INCREASE

A JUMP of some $50,000,000 in the revenue of the Dominion for the last 10 months is indicated by the financial statement covering that period issued on Feb. 9. The total for the 10 months was $187,903,565. The increase for the month of January, when $21,047,216 was taken in, was about $4,000,000. The increase in general expenditure during the 10 months was about $10,000,000, the total expenditure on capital and war accounts being $215,521,914 for the 10 months, and $26,318,529 for January. On consolidated fund the expenditure for the 10 months was $187,903,565, and $18,882,897 during January. In the 10 months' total the principal items of revenue were $108,868,302 from customs, $20,561,709 from excise, $15,881,627 from post office revenues, and $21,701,730 from railways, canals and public works. There was an increase of some $23,000,000 in the net debt which is now $745,438,869.

Steam Boiler Safety Valves.—In any safety valve there are three factors which affect the rate of flow over the seat that are characteristics of the seat itself, namely, the vertical lift, the seat angle, and the contour of approach to the seat. The flat seat is adapted to open the largest area per unit of vertical lift and should be employed—other conditions being equal.

Operators' Instruction Course

CONCERNING INDICATOR DIAGRAMS—V.

THE present article concludes the series on Indicator Diagrams, and in view of the fact that those preceding have dealt almost entirely with their reference to the steam engine, it seems fitting that in the present instance something should be said concerning indicator diagrams in connection with modern gas and oil engines.

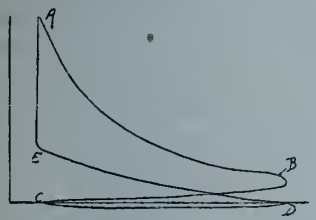


FIG. 26.

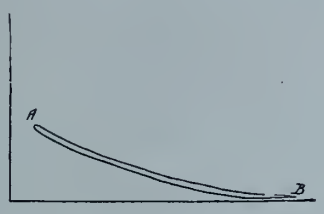

FIG. 27.

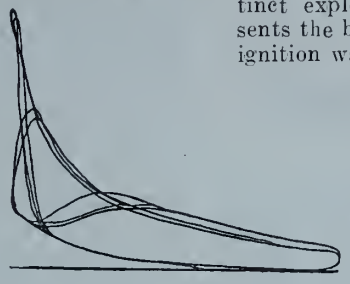

FIG. 28.

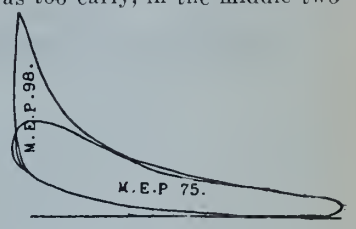

FIG. 29.

Indicating Gas Engines

While the indicator is necessary for determining the I.H.P. and efficiency of gas engines, it can also be made to serve a large number of other useful purposes when the right kind of indicator is used, and when its many applications are fully understood. For instance, the gas engine indicator can be made to show the following: Timing of ignition; overrichness or leanness of the mixture for different conditions of atmospheric pressure and humidity; the proper timing of the exhaust and inlet valve events; whether the exhaust and inlet valve passages are of the right proportion or are clogged up due to deposits of soot, or have too many bends, and other uses as mentioned in the following description.

A well-known type indicator, especially adapted for indicating gas engines, embodies in its make-up two cylinders and two pistons. The regular piston has an area of one-half square inch, but by removing this piston and inserting a smaller one in a sleeve in the main cylinder, the effective area of the piston is reduced to one-quarter square inch, thus giving double the range of pressure for the same travel of the pencil point. In other words, if a 100-lb. spring is used in connection with the ¼-inch piston, each inch height of the indicator card represents 200 lbs. pressure. As the pressure in gas engines often runs to four or five hundred pounds, the advantage of these two pistons will be apparent.

Fig. 26 shows a typical gas engine card taken with a heavy spring, except that the suction and exhaust lines have been exaggerated so as to be visible. The line C to D represents the suction stroke. If this line drops very much below the atmospheric line, it indicates that the area of the suction pipe is too small, that the valve opening is too small, or it may be caused by too many bends or short elbows in the suction pipe; DE represents the compression line. At E the explosion occurs, and the pressure jumps quickly up to the point A. Line AB represents the expansion of the gases. At B the exhaust valve opens. This should be at from 85 to 90 per cent. of the stroke. Exhaust or pushing out of the burned gases, is represented by BC. The exhaust line should be close to the atmospheric line. If the line BC is too high it may indicate that the exhaust line is choked, or it may also be due to the cause mentioned above concerning the suction line. It should be remembered that the area included between the suction and exhaust line represents negative work, therefore this area should be kept as small as possible. The above card is from a four-cycle engine.

Fig. 27 shows a card for the idle stroke of a hit-or-miss governed engine. The top line represents compression and the lower line expansion. If there are no leaks and the cylinder is not cooled too much, these lines should very nearly coincide. Any area between them represents lost work.

Fig. 28 is a card showing eight distinct explosions, none of which represents the best cycle. In the tallest cards, ignition was too early, in the middle two cards it was too late, and in the lowest cards it was very late.

Fig. 29 shows two explosions. The card with the high point represents a correct setting of the valves and mixture of the gases. The lower card was taken when the mixture was too rich in gas, showing that there was a loss of almost 25 per cent. in power by not having the proper mixture.

Fig. 30 shows one perfect explosion and five in which the ignition was too late.

Figs. 28, 29 and 30 are actual cards taken on an engine, while Fig. 26 is an ideal card with suction line exaggerated. Comparing the actual cards, it will be noted that the suction and exhaust lines do not show up. This shows the necessity of using light springs for determining setting of valves.

Fig. 31 shows a card in which pre-ignition occurred. From A to B is the suction stroke, while BC represents the beginning of the compression curve; at C, ignition occurred, and the pressure rose

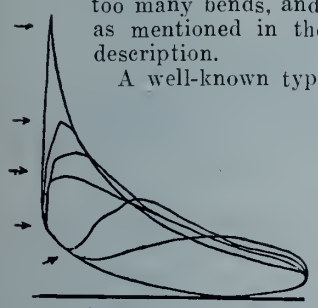

FIG. 30.

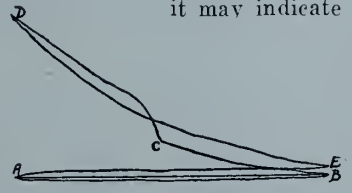

FIG. 31.

FIG. 32.

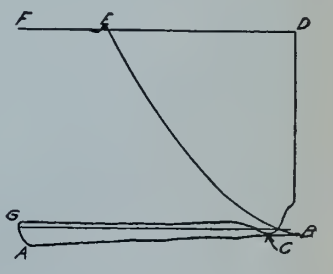

FIG. 33.

to the point D while the piston was still traveling forward. From D the gases expanded to E in the usual expansion curve. The card shows that very little useful work is delivered. Pre-ignition may be caused by using gas too rich in hydrogen which ignites without the application of a spark, due to the increase in heat while being compressed. It may also be caused by particles of carbon or other solid matter which are lodged in the cylinder and become incandescent under the temperature of compression, or when any of the water-cooled parts are insufficiently cooled, due to the use of too little water or water at too high a temperature.

Fig. 32 shows the type of card given when back-firing occurs. From A to B

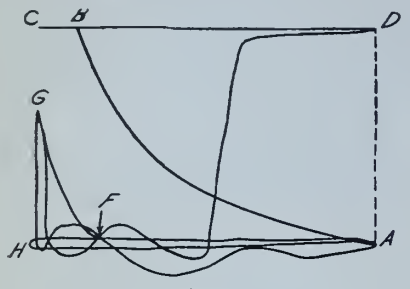

FIG. 34.

represents the ordinary suction stroke, but at F the gas was ignited before the suction stroke was completed, causing the pressure to rise to B. The partly consumed gases were then compressed up to D and expanded again practically along the same line. The result of a back fire is not only the loss of power in the stroke in question but usually causes a mis-fire on the next succeeding power stroke because an ignition takes place while the intake valve is still open, the burned gases go back into the intake pipe and foul the gases contained in it. This is shown by the idle stroke CE in the indicator card.

A back fire may be caused by badly timed ignition, by a leaky inlet valve, in which case the gas in the intake pipe is ignited during the previous explosion

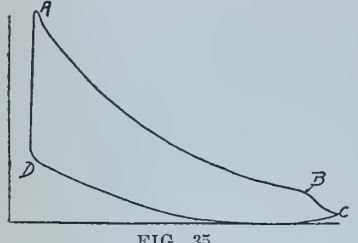

FIG. 35.

stroke, or it may be caused by using a gas of too lean a nature, so that the gas burns very slowly and continues to burn in exhaust stroke. A part of this gas is still burning in the clearance space when the next charge is drawn in. Again, if there are any pockets or small passages, the gas in the pocket may be cooled to a point where it does not ignite readily but becomes heated and ignites in the latter part of the expansion stroke and continues to burn until the succeeding suction stroke, when the incoming charge is ignited.

Fig. 33 shows a typical card taken with a Trill indicator having a one-half inch piston and an eight-pound spring. The line AB is the suction, and as this is only a trifle below the atmospheric line, it will be seen that the intake ports are ample and that no vacuum or negative pressure is produced. The line BE represents compression. This is not shown up to the limit of compression for the reason that the indicator is provided with a stop which limits the travel of the indicator piston and prevents damage to the instrument. Therefore, as soon as the pressure reached the point E, the pencil could not move any further and it traces a straight line to the end of the stroke at F. From F to D explosion and expansion of the gas have occurred, but as the pressures are still above the limit of the spring only a horizontal line is drawn. At D, however, the pressure falls to within the range of the indicator and the quick drop in pressure shown by the vertical line DC is proof that the burnt gases are being expelled from the cylinder without producing any back pressure. From C to G is the exhaust line, during which period the gases are expelled from the cylinder. As this line is only slightly above the atmospheric, little power is being lost. The card is practically a perfect one for a light spring, showing that all of the events occurred at the right time.

Fig. 34 shows a very bad card taken with a light spring and will also serve to show how valuable a good indicator is in detecting improper setting of valves, timing of explosions, etc. From H to A represents the suction stroke, and A to B the compression. It will be seen that the stop on the indicator is reached at B, and a horizontal line is traced to the end of the stroke. From C to D the pressures are above the range of the indicator. If the exhaust valve had been set properly, the line at D would have followed the dotted line similar to the straight vertical line shown in Fig. 33, but the exhaust valve did not open soon enough, therefore the pressure did not start to drop until nearly one-third of the exhaust stroke had been completed. Furthermore, the exhaust valve besides opening too late, closed too soon; this is shown by the rising pressure from F to G, indicating that instead of all of the burned gas being expelled, part of it was entrapped and compressed. This used gas mixed with the new charge fouls it Line GH shows that, as soon as the intake valve opened, this burned gas expanded back into the intake pipe, allowing the pressure to drop down to atmosphere.

All of the above cards not only represent a direct loss in power, but they also interfere with the operation of engines especially when they are direct connected to generators. Pre-ignition and missed strokes tend to slow down the engine, causing a variation in voltage of the generator which, if it is supplying a lighting current, introduces annoying flickering of the lights, or if the engines are direct connected to alternators which are running in parallel these momentary changes in angular velocity set up cross currents and introduce hunting between the generators.

It will thus be apparent that if maximum power and satisfactory operation

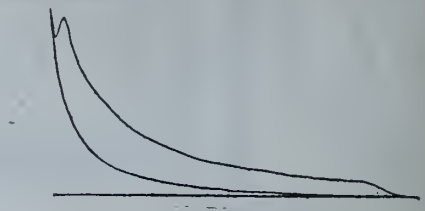

FIG. 36. POWER CARD.

are to be obtained from any gas engine it is absolutely necessary that it be indicated occasionally, for, even though the valves may be properly set when the engine is first set up, they are liable to become fouled and will stick, passages will become obstructed and other troubles will creep in unless they are periodically looked after.

The foregoing discussion applies mainly to engines working on the four-stroke cycle. Fig. 35 represents a typical card from a two-port, two-cycle engine. It will be noticed that the suc-

FIG. 37. SCAVENGING CARD.

tion and exhaust lines are absent in this card, the suction stroke being completed in an enclosed crank case or separate cylinder or pump. Point C represents the inlet of the mixture; CD is the compression line; D the point of ignition; DA represents the increase of pressure due to explosion; AB the expansion; at B the exhaust valve opens, and the line BC represents falling pressure due to exhaust. The card of the two-cycle engine would be modified practically the same as that of the four-cycle engine due to improper timing of the ignition valve events.

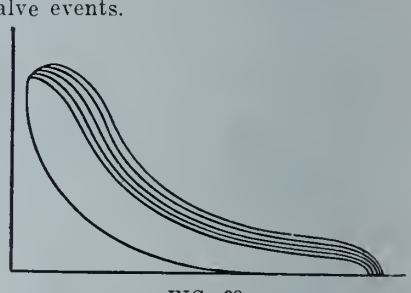

FIG. 28.

By taking indicator cards on gas engines it is possible to so time all the events that maximum power will be obtained. The mixture can be so regulated that maximum explosion pressure is obtained. The effects of different temperatures of jacket water can also be studied.

The horse-power of a single acting, single cylinder four-cycle gas engine is given by the following:—

$$\text{H. P.} = \frac{\text{PLAN.}}{4 \times 33{,}000}$$

Where P = mean effective pressure in lbs. per sq. inch = the mean ordinate of the indicator card × the scale of spring used; L = length of engine stroke in feet; A = area of piston in sq. inches; N = number of single strokes per minute = 2 × r.p.m. In the case of a hit or miss engine, N should be taken as the number of explosions per minute and the 4 omitted from the formula.

For single acting, single cylinder, two-cycle engines, the following formula should be use:

$$\text{H. P.} = \frac{\text{PLAN.}}{2 \times 33{,}000}$$

Figs. 36 and 37 are characteristic cards of one of the latest types of high compression, two cycle oil engines. These are actual cards taken on a Nordberg engine recently installed. Fig. 36 represents the power card, a 300 lbs. spring representing an m.e.p. of 75.5.

Fig. 37 is a scavenging card taken with a 10 lbs. spring, and represents the cycle of compression of the scavenging air on the crank side of the engine. This card gives the characteristics of the scavenging air compressed on the exhaust stroke and forced into the cylinder when the exhaust port opens. The purpose of this scavenging air is to remove the products of combustion and fill the cylinder with fresh air as quickly as possible. It is important that scavenging air valves and events be set and regulated by indicator card.

The diagrams Fig. 38 are characteristic of the modern type of Nordberg-Carels Diesel engine, and illustrate the result due to the variation of the governor adjustment, which varies the injection of the fuel.

Indicator Spring Data

Scale of Spring	Steam Pressures Recommended Not over 150 R.P.M.	Not over 300 R.P.M.
8	12	8
10	18	12
12	22	16
16	30	24
20	40	32
30	70	55

150	300	300
200	400	400

The above are conservative figures furnished by the Trill Indicator Co. They state, however, that they are willing to guarantee their instruments up to 600 r.p.m.

EXHAUST MUFFLERS FOR OIL ENGINES

IN a note on the operation of a small Diesel engine plant which recently appeared in the "Electrical World," a description is given of a method of muffling the exhaust of the engines. When the engines were placed in operation, the noise of the exhaust and the vibration it caused brought up an operating problem which required considerable study, and was worked out by the construction of special mufflers. The location of a deep well between the two units made it impossible to pipe the exhaust to one muffler, so that two were installed at opposite sides of the station. These were constructed of heavily reinforced concrete with a conical-shaped roof and steel stack projecting 3 ft. out of the top. They are about 8 ft. in outside diameter and 10 ft. high to the top of the concrete, and set on six concrete piles instead of solid foundation, to prevent vibration. The size of the mufflers was determined by the piston displacement and scavenger air volumes per stroke.

The exhaust enters at the bottom and on the side, where a circular brickwork makes the gases whirl about the centre of the muffler. This circular motion has a tendency "to pull a vacuum" behind the gases. On top of the brickwork forming the first stage is a system of grate bars, and on top of these are ordinary brick in layers which act as a baffle to release the exhaust gases gradually and reduce the noise. On top of this is a fine wire screen with a layer of crushed stone further to reduce the exhaust report. The conical-shaped top is merely to keep the rain out. Connection to the sewer is made to drain the condensation on the interior.

In order to keep the concrete from getting too hot when the engines are running continuously under heavy load, a ½ in. pipe is run out and tapped into the exhaust pipe just outside the muffler, and a small amount of water turned on. This water is carried into the muffler as steam, and keeps the temperature down. Frequently an accumulation of carbon in the muffler will catch fire. This is allowed to burn out for a while, or until the concrete begins to get too hot, and then water is turned on full in the small pipe to put the fire out. This process makes the muffler self-cleaning. The mufflers are so effective that the exhaust cannot be heard or any vibration of the air or ground felt when standing immediately beside them. When both engines are running, their intake exhausts about 4,000 cub. ft. of air per minute from the room.

After the installation was made, it was soon found to be practically impossible to keep the engine-room warm enough in winter. This was overcome by making a special air intake to the room, and at the same time utilising a portion of the waste heat of the exhaust. The iron exhaust pipe for one engine on the outside of the station was bricked in, leaving about a 6-in. space around the pipe and with the outer end of this brickwork open. The inner end of this brickwork opens into the floor of the engine-room right at the intake ports of the engine. The air is thus drawn in over the hot exhaust pipe, providing a source of hot air to produce a better mixture in the cylinder, and also overcoming the draught of warm air from the room. The exhaust pipe from the other engine is carried through the oil-tank room, and the whole room is used as an intake flue for the engine. Incidentally this heat in the oil-tank rooms keeps the oil in good condition in the coldest weather.

C. A. S. E AND GRADED CERTIFICATES

TWO meetings under the auspices of the Canadian Association of Stationary Engineers were held on January 29 in the Orange Hall, North James street, Hamilton, Ont. Both were of importance to members of the organization, and concerned the issuing of graded certificates to stationary engineers. The afternoon session was devoted to a joint conference, the individual constitution of which was as follows: W. G. Forbes, Montreal, president; John W. Hale, Hamilton, secretary; Robert Dyson, Guelph, past president; Rodger F. Gofton, Kitchener, vice-president; A. W. Heath, Hamilton, treasurer; William Cooke, Belleville, conductor; John W. Beasley, Chatham, doorkeeper; the Provincial Board of Stationary Engineers' Examiners, W. C. McGhie, Charles Mossley and Wm. Corrigan, also Dr. Ridell, superintendent, Trades and Labor Branch, Department of Public Works, all of Toronto. Hon. F. S. McDiarmid, Minister of Public Works, Province of Ontario, was unable to attend.

As a result of the deliberations, draft resolutions were framed regarding the grading of certificates and licenses for stationary engineers. These provide for four certificates according to qualification, namely, first, second and third class, also extra by virtue of merit. The decision arrived at will be duly forwarded to the Provincial Minister of Public Works, with a request that the Ontario Stationary Engineers' Act be so amended.

Dr. Ridell congratulated those present upon the intelligence displayed during the conference, and said, though the meeting was unanimous in the adoption of graded certificates, naturally it was to be expected that other districts would be adverse to the change. He thought some would disagree because of labor's reluctance to agree to a policy whereby a division would be made in the ranks, because some would say it savored of striking at the solidarity of labor. His view was that the grading tended for the men's greater efficiency and better collective bargaining. He also thought there was a better time in store for labor after the war, for the second industrial evolution in England was bound to react in Canada in th enear future. "If we can read the signs of the times, shorter hours, higher wages, and better conditions are inevitable for labor, for the workers of the land will be more efficiently trained, and consequently labor must benefit," he said. Concluding, the speaker said he couldn't say that graded certificates would be concurred in by the Government, but he could say that if the engineers of Ontario wanted it, they could get legislation if they went the right way about it. If adopted, the Government would make the scheme self-sustaining.

Question and Answer Section

Heating System Back Pressure.—When extracting steam from a turbine, what is the economical limit to back pressure in the heating system?—N. E. A.

The economical limit depends entirely on the design of the turbine and the local conditions under which it is operating. Bleeder turbines may be designed for most economical performance when bleeding at almost any given pressure. With a suitably designed turbine and favorable operating conditions, it would be economical to extract steam at pressures up to within roughly 25 per cent. of the throttle pressure.

* * *

Live Steam in Heating System.—When would it be economical to use live steam in a heating system, rather than bleed the turbine?—N. E. A.

It would be preferable to use live steam in a heating system rather than bleed from the turbine, except when the design of the turbine and the conditions under which it operates are such that when bleeding direct from the boilers and operating the turbine straight condensing, the total amount of steam used will not exceed that required by the turbine when operating as a bleeder.

* * *

Boiler Horse-Power.—I should like to have you explain by what means the horse-power of steam boilers is determined?—T. W.

A somewhat similar question was asked and answered in our issue of September, 1916—Question and Answer Section—the only difference being that tractor boilers, flue boilers, and water-tube boilers were specifically referred to. The information then furnished meets the present query fully, and is reproduced as follows:—Boiler horse-power, it may be stated at the outset, is a misnomer, and should be reckoned as simply a convenient and compact means of making comparison of boiler capacities for commercial purposes. A boiler, no matter its classification, form or type, be it horizontal or vertical, smoke-tube or water-tube, internally or externally fired, designed and constructed for high, medium or low pressure, and be it installed ashore or aboard ship, is essentially a vessel in which steam is generated. The power is in the steam, and little exemplification of that power is to be had as far as the boiler is concerned except when the latter blows up, and we have what is known as a boiler explosion of lesser or greater magnitude. On this continent the accepted commercial rating of one boiler horse-power is taken to represent an evaporation of 30 pounds of water per hour from a feed water temperature of 100 degrees Fah. into steam at 70 pounds gauge pressure, this being considered as equal to the evaporation of 34½ pounds of water from a temperature of feed water of 212 degrees Fah. (boiling point of water) into steam at the same temperature. Further, a boiler rated at a given horse-power is expected to demonstrate same with easy firing, moderate draught, with ordinary fuel, and to show at least a fair measure of economy. Again, the boiler should be capable of developing from one-fourth to one-third in excess of its rated power if called upon in an emergency. Tractor, flue, water-tube, or for that matter any classification of boiler come under this commercial horse-power rating if their manufacturer so will it, at the same time there is nothing compulsory about acceptance being all inclusive, in which circumstance a boiler-maker may adopt a rating to suit himself and that of his clients. The boiler generates steam, the engine develops the power, and the principal concern is in our seeing to it that the boiler capacity for steam generation is ample for the duty that the engine has to perform, and that the greatest economy of fuel is being realized. Rough-and-ready rules for computing boiler ratings may be taken as 12 sq. ft. of heating surface, or one-third sq. ft. of grate area per boiler horse-power respectively.

* * *

Drying Out A. C. Generator.—In the Question and Answer Section of your November issue, methods of satisfactorily drying out direct current generators were among other things specially featured. What method should be employed for drying out an alternating current generator and a synchronous motor respectively.—G. E. R.

A generator may be dried out simply by driving the rotor at normal speed for several days by its prime mover. However, if excitation is applied in addition, the process will be accelerated. In this case, a generator of less than 6600 terminal volts should be run at normal speed with the armature windings short circuited and with a belt excitation sufficient to give approximately 110 per cent. normal current in the armature windings. For a generator of 6600 terminal volts or more, it is recommended that the drying-out process be conducted by alternate runs with the armature windings short circuited (and excited as previously described) and the windings open circuited (and excited to give approximately 110 per cent. normal voltage. The former dries the insulation from the inside outward, and the latter the reverse. This alteration should be kept up until the insulation resistance, as measured by a megger, becomes fairly constant. An empirical rule which has proved very satisfactory is that the insulation resistance of the armature windings should be approximately equal to three times the terminal voltage by the kilovolt-ampere rating. For example, assume a 10,000-kv-a., 6600-volt generator, then the insulation resistance should be approximately

$$\frac{3 \times 6600}{10{,}000} = 1.98 \text{ megohms.}$$

While this applies to the armature windings only, it may be used as an indication of the completion of the drying out process, for stator and rotor windings are dried at the same time.

For drying out a synchronous motor, the methods described for alternating-current generators cannot, generally speaking, be applied to synchronous motors and frequency changers. If a source of direct current is available, the field and armature windings may be connected in series or parallel depending on the machine and current passed through, until a temperature of approximately 65 deg. C by thermometer is reached. This should be continued until the insulation resistance by megger attains the value designated in the alternator query reply, or until it becomes constant. Another method is to dry out the machine by an application of external heat. For the source of heat, an oven may be used, or a number of coils of steam pipe, which with the motor are to be enclosed in a box. Openings in the top and bottom of the box should be provided to give circulation, the moisture being carried off by the hot air.

* * *

Boiler Horse-Power.—To settle a bet, will you kindly calculate the horse-power of a horizontal return tubular boiler, the mean diameter of which is 5 ft. and the length 14 ft. There are ninety 3-inch smoke tubes?—R. K.

The total heating surface may be reckoned as consisting of the lower half of the boiler shell plus the surface of the tubes, and this divided by 10-12 or 15, being representative of sq. ft. of heating surface per boiler horse-power in more or less common use, will give a variety of ratings, on the middle one of which a mutual agreement may be come to, and the bet be called off. The details

of the calculation are given below. It will do no harm, however, if the bettors read carefully the reply given the boiler horse-power query of T. W. in this same issue.

Heating surface of lower half of boiler shell $= \frac{5 \times 3.1416}{2} \times 14 = 109.95$ sq. ft.

Heating surface of ninety 3-inch tubes, each 14 ft. long $= 90 \times \frac{3 \times 3.1416 \times 14}{12}$ $= 989.60$ sq. ft.

Boiler shell heating surface plus tube heating surface $= 109.95 + 989.60 = 1099.55$ sq. ft. total heating surface.

Total heating surface divided by 10-12 and 15, give boiler horse-power respectively of 109.95, 91.63, and 73.3.

* * *

Boiler Quivering Under Steam.—We have a 60-inch diameter by 14 ft. long return tubular boiler, without dome, which supplies steam to a horizontal Corliss engine whose cylinder is 16-inches in diameter by 30-inches stroke. The engine load averages about 100 horse power. After running about two hours in the morning, the boiler begins to quiver and continues to jump so to speak, during the rest of the day, but to a greater degree when a fresh fire is put in. I have asked several engineers for an expression of opinion as to the cause of the quivering but have been unable to secure a satisfactory explanation so far. I shall be glad to have you give me a reason for this peculiar and altogether startling phenomenon, accompanied by a suggestion or suggestions as to how the uncanny display may be brought to a close.—C.M.C.

The fact that the trouble gets worse when fresh fires are put on would point to it being due in some way to boiler conditions. The steam consumption of an engine of this type running non-condensing would be well over 20 lbs. per hour, which with possible condensation losses in piping would approach 30 lbs. of steam per hour. As a boiler of the size and type mentioned would have a normal capacity of about 60 boiler horse power i.e. 30 lbs. of water per horse power, it may quite well be running much over capacity. The absence of a steam dome, along with impure water and a heavy deposit of scale would cause sufficient priming to give rise to the quivering mentioned especially if the steam pipe have sharp bends near the engine and no separator is fitted: the quick cut-off of the Corliss gear would cause vibration through the sudden stoppage of the flow of steam which would be still worse if the steam pipe is of too small a diameter. The increased vibration after firing up is probably due to increased priming resulting from the drop in pressure while the fresh fire is burning up.

To remedy the present conditions, the water should be treated to insure a proper degree of purity, the steam pipes should be covered with the best material available, and a receiver separator installed close to the engine. Sharp bends or elbows should be made easy and if possible an expansion bend put in the steam pipe near the boiler. These are mentioned as meantime remedies short of an actual increase in boiler plant capacity.

* * *

Belt Lengths.—It occurs to me that I may at some time or another be called upon to order the necessary belting for either an open or crossed drive, and, in order to be prepared for such eventualities, how may I arrive at their exact length?—T. W.

On all ordinary open belt drives, such as are found in machine shops, the required length of belt can be calculated with sufficient accuracy by adding half the diameter of one pulley to half the diameter of the other, both in inches, multiplying this by 3 1-7 and dividing by 12 to bring the result to feet. Now add to this twice the distance between centres, with an extra allowance of, say, 1 in. for each 10 feet of belt, where width is from 2 in. to 4 in. Belts less than 2 in. wide can do with a less allowance, while belts over 4 in. require 1½ in. to 2 in. allowance. Such a method would give accurate enough results for pulleys up to, say, 20 ft. apart, and of approximately equal diameters. In cases where there is a great difference in the diameters of the pulleys additional allowance must be made, also when the shafts are far apart, the amount necessary to provide for sag may be considerable. Where crossed belts are used, the length of the straight parts between the pulleys may be calculated approximately by adding the square of the large pulley diameter to the square of the distance between centres, and taking the square root of the result, which will give a safe length for one of the diagonal lengths. In ordering belting, as in many other supplies, it is best to be on the safe side, and in many shops a roll of belting of each size is kept in stock. If drives are important enough to demand special belts, a steel tape and a capable millwright offer the quickest and most accurate results in measuring.

* * *

Steam Engine Horse-Power.—What is the usual procedure followed in figuring out the horsepower being developed by, say, a single cylinder, horizontal or vertical type steam engine, and what additional calculations are required in the case of an engine having two or more cylinders; a compound or triple expansion engine, for instance.—T. W.

In order to calculate the horse-power which is being developed by a particular engine, it is necessary to know the mean effective pressure which is exerted on the piston throughout the length of its stroke. This is obtained from the indicator diagrams which are taken from each end of the cylinder during a number of strokes to get an average diagram. Diagrams should be taken from both ends simultaneously if accurate results are required, as the loss of area on one side of the piston due to the piston rod, makes an appreciable difference in the results. Assuming that cards are taken from each end, the average height of the diagram in inches is found in the usual manner, which, when multiplied by the strength of the spring used, gives the mean effective pressure or m.e.p.

The "plan" formula is the most easily remembered method of figuring the power. It is as follows:—

$\frac{\text{PLAN}}{33{,}000}$ = indicated horse-power where P is the mean effective pressure in lbs. per sq. in., L is the stroke in feet, A is the area of the piston on which the pressure acts, and N is the number of times per minute that the pressure is exerted on the piston. In the case of a single cylinder engine 12 in. dia. x 18 in. stroke, running at 120 revs. per min., the front end card may have given a m.e.p. of 65 lbs. per sq. in., and the rear end, 70 lbs. per sq. in. With a piston rod diameter of 2 in., the power developed in the front end would be, 65 × stroke in feet, 1½ × area, 113.1 — 3.14 × number of revolutions per min., 120, all to be divided by 33,000, thus $65 \times 1\frac{1}{2} \times 109.96 \times 120 = 1{,}286{,}532$, which, divided by 33,000 = 38.9. The power developed in the rear end differs to the extent of the piston rod area which is not deducted, thus $65 \times 1\frac{1}{2} \times 113.1 \times 120 = 1{,}323{,}270$, which, divided by 33,000 = 40. Adding the two ends together gives $40 + 38.9 \div 2 = 39.45$ I.H.P. In the case of the front end, 3.14 is the area of the 2 in. dia. piston rod, which is deducted from the total area of the 12 in. piston. Where a tail rod of equal diameter to the piston rod is used, the effective areas on either side of the piston are the same, and if the m.e.p. on each end is equal, the power can be found in one calculation by using twice the number of revolutions, which is the number of times the power is exerted on the shaft in one minute.

In the engines having two or more cylinders, the additional calculations apart from the m.e.p. which is found from the diagrams, would be the figuring of the piston diameters, which would be increased as the absolute steam pressure dropped in each cylinder, the stroke of each cylinder being the same.

FAILURE of material owing to it being unable to withstand the action of a suddenly applied shock is quite frequently met with. The importance of testing the capability of the material to the resistance of shock stresses is not yet fully recognized by engineers and machine designers. It is well worth the trouble to make an approximate analysis of the different stresses that are applied to the steel parts of any particular machine. It will be found that in nine-tenths of the machines in use fully 50 per cent. of the stresses are due to constant shock, and at least a further 25 per cent. are due to intermittent shock. Therefore, if 75 per cent. of the stresses applied to steel parts are due to shock, it is obviously essential that some form of shock or impact test should be applied.

Steam Power Plant Auxiliaries

STEAM SEPARATORS—1.

WET steam is probably the most troublesome feature of steam power plant operation with which engineers have to contend. Not only is it dangerous through giving rise to water hammer with breakdowns and occasional loss of life, but all the time it is a source of continual loss in the efficiency at which a plant operates. Even though the steam as it leaves the boiler is comparatively free from moisture, it has been found as a result of investigations that about 3 per cent. of water is nearly always present in the steam as it enters the engine, and that in some cases it may exceed 50 per cent., part of this being water carried over from the boiler and part due to condensation.

Causes of Wet Steam

Various conditions are responsible for the presence of water in steam, chief of these being priming of the boiler, and excessive condensation in the pipe line. In the case of the boiler, a small percentage of water is always present in the steam unless the rate of evaporation is extremely low; rapid steaming boilers being much more prone to priming than the less modern cylindrical types with or without tubes, although any sudden reduction of pressure is liable to cause priming despite the provision of large steam-liberating surface and water-carrying capacity. In any case, a proportion of solid water may enter the pipe line along with the steam, forming a slug, which is carried along with the steam at a high velocity until it reaches the engine after which something unfortunate is liable to happen.

Under normal conditions, an uncovered steam pipe will condense fully three-quarters of a pound of steam per hour for each square foot of surface. Properly covered pipes reduce this to a great extent but are unable to prevent a degree of condensation sufficient to saturate the steam so that a serious loss of efficiency is unavoidable in any engine working under these conditions, unless the moisture and water be almost entirely removed from the steam. Even where the principle on which a separator works may not be quite correct, its value is frequently increased by the provision of a receiver of suitable volume which not only gives the moisture an opportunity to settle by gravity, but also cushions the pulsations of the steam in the pipe caused by the opening and closing of the valve in the engine cylinder.

Necessity for Separators

The detrimental effect of wet steam on cylinder lubrication in piston engines, and on the blades of steam turbines has been proven frequently and

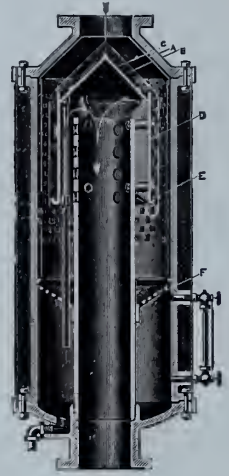

FIG. 1. VERTICAL STYLE SWEET'S SEPARATOR.

the economy of oil and upkeep in both types of prime movers is sufficient in many cases to justify the installation of a steam separator. When to these features is added that of freedom from breakdown due to water hammer, the vital necessity of an efficient steam

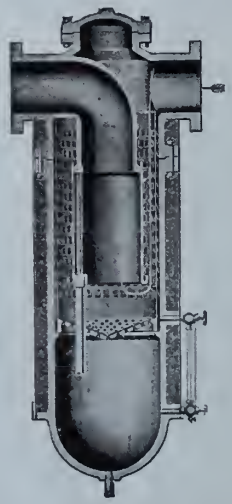

FIG. 2. HORIZONTAL STYLE SWEET'S SEPARATOR.

separator becomes more and more apparent.

The recognized standard of efficiency for a steam separator is the ability to separate not less than 99.5 per cent. of moisture from steam depending upon circumstances, good modern practice enabling higher results to be obtained. Other features deserving consideration are, the minimum reduction of pressure in currents passing through the separator, simplicity and durability of construction, compactness, and suitability for operation under high pressures.

Sweet's Separator

The design of this separator is based on the fact that water may be removed from steam by passing the steam over a corrugated or rough surface, to which the little particles of water adhere. The surface employed is broken up in such a manner that the little particles are immediately conducted out of the steam current, and kept from further contact with it. The capillary principle, which is the foundation of the design, is most efficiently employed when the surface is at a maximum, and the various types of Sweet's Separator, as built by the Direct Separator Co., Syracuse, N.Y., are provided with liberal separating surface and large space for steam storage and water chamber, the latter feature making it of value as a steam receiver to prevent vibration etc.

The vertical type is illustrated in Fig. 1. The accumulated moisture around the walls of the steam pipe is caught by the upper edge of cone A and carried down back of a lining to the water chamber. The current of steam entering the separator impinges upon the conical surface composed of solid plate C covered with sieve B, through which water may freely pass, but from which it cannot readily escape. Passing through the sieve and depositing on the solid surface of the cone C this water is carried by conductors to the water chambers. By means of the cone the column of steam is changed to an annular ring, which is comparatively thin even while the full area of the pipe is maintained. The steam upon the outside of this ring comes in contact with the lining of the shell, which is a sieve of the same character as at B, and which catches and entrains any water which may be contained in that portion of the current. There is also provided a trough at lower edge of inverted cup, which leads all the water that may adhere to its surface down to the conductors to the water chamber. The current of steam passes through the passages in-

dicated by the white lines, and is subjected to a whip-snapping action which will throw off any moisture that has not been caught by the surface over which it has passed. The diaphragm F pre-

FIG 3. WEBSTER VERTICAL SEPARATOR SHOWING BAFFLES AND GROOVES.

ents the steam from picking any water ut of the water chamber.

The horizontal separator, Fig. 2, perates in substantially the same manner as the vertical style, the moisture n the bottom of the inlet pipe being aught by the shelf and cone provided,

G. 5. HOPPES VERTICAL SEPARATOR, SHOWING CONE AND INTERCEPTING TROUGHS.

om which it finds its way to the back the lining and to the water chamber e moisture adhering to the elbow passes over its surface and is caught by the trough provided, whence it passes through conductors to the water space. The steam then passes in an annular ring through the space indicated by white lines and is acted upon the same as in the vertical style.

In the smaller sizes, the separating plates are made of copper, and in the larger sizes a special non-corrosive sheet iron is used. The smallest size made weighs 50 lbs., and the largest 24,000 lbs.

Webster Separators

Eleven different styles of these separators are built by Darling Bros., Montreal, the wide variety enabling piping and pressure conditions to be conveniently met in installations of all kinds. The standard types are also modified to form receiver separators which provide receiver wells of unusual dimensions to receive large slugs of water from excessive boiler priming or unusual condensation in low-pressure service and also tend to equalize steam pressures at the point of delivery because of the large quantities of steam which they store.

Cast iron shells are used in all of the standard types, of which the vertical and horizontal designs are illustrated in Figs. 3 and 4 respectively. In the former, the steam is directed into a central space which reduces the velocity considerably to assist in separation, the cast iron baffles which extend across this space causing a sudden change of direction of flow with consequent freeing of entrained moisture. The upper walls of the central space are provided with sloping grooves which complete the process of separation as the steam passes over them on its way to the outlet at the lower end.

The horizontal separator, Fig. 4, is provided with a central baffle plate with collecting ribs on the face against which the steam impinges, the moisture dropping from the ribs into the collecting space below. The lower ends of the ribs are connected to a diaphragm which prevents free passage of the of the steam below the baffle, suitable spaces around the sides and top being provided for the passage of the steam.

Hoppes Separator

This apparatus has been designed on the principle of reduced steam velocity with a complete absence of tortuous passages, baffles, abrupt reversals of direction etc. To accomplish this object the inlet passage is gradually enlarged into the expanding chamber where the water is deposited, being then gradually reduced to the capacity of the steam

FIG. 4. HORIZONTAL TYPE OF WEBSTER SEPARATOR WITH VERTICAL RIBBED BAFFLE.

pipe; the working areas nowhere are less than three and one-half times the area of the pipe.

The vertical type is shown in Fig. 5 from which it will be seen that no obstructions to the free flow of the steam are offered, nor are there any edges

FIG. 6. HOPPES HORIZONTAL SEPARATOR WITH SEPARATE TROUGHS TO EACH PASSAGE.

from which the water of entrainment can be blown off and atomized. The entrainment follows the surface to the

lowest part where it is intercepted by water in the bottom. Water which strikes the cone on entering is also collected in a trough, partly filled with water, being then carried to the bottom by the pipe shown. The dry steam

FIG. 7. SMART-TURNER SEPARATOR WITH CENTRE BAFFLE AND GROOVED WALLS.

escapes through the upper end of the outlet pipe which projects up underneath the cone.

The horizontal separator Fig. 6, is so designed that the steam may flow through it in either direction. The inlet and outlet ports are separated by a vertical division plate which extends down to where separate gutters surround the inlet and outlet passages. These are partly filled with water to intercept all water of entrainment fol-

FIG. 8. HORIZONTAL STRONG SEPARATOR SHOWING LIP FOR TRAPPING CONDENSATION.

lowing the surface, while the downward plunge of the steam entering the steam chamber throws the water of saturation to the bottom of the separator. The excess water is carried from the troughs by pipes to the bottom of the separators from which it is trapped in the usual way.

These separators are built by the Hoppes Mfg. Co., Springfield, O., in sizes from 1 in. to 9 in. inclusive and suitable for working pressures of 200 lbs. per sq. in.

Smart-Turner Separator

This apparatus is of the impact baffle type, in which change of direction along with collecting surfaces is relied upon to extract the contained moisture. It is of the horizontal type, suited for use in either direction (see Fig. 7). The steam inlet opens directly into an expansion space, in which is placed a ribbed baffle plate, supported on a gutter-shaped divi-

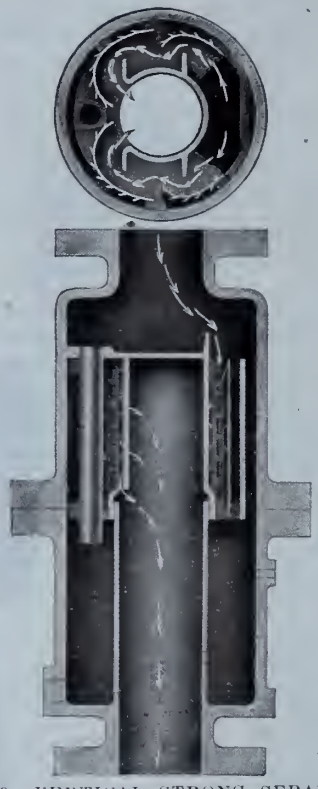

FIG. 9. VERTICAL STRONG SEPARATOR WITH LIP ON TOP AND DRAIN PIPE TO WELL.

sion plate extending across the space. After impinging on the baffle and depositing moisture, the steam passes over and around, thus coming in contact with a suspended baffle on top, and numerous vertical ribs or grooves formed on the side walls in such a way as to carry the collected moisture down past the division plate into the collecting well, from whence it is drained by trap in the usual way.

These separators are built by the Smart-Turner Machine Co., Hamilton, Ont., in sizes from 2 in. to 12 in.

Strong Separators

The horizontal and vertical types of this device are shown in Figs. 8 and 9, special attention having been given to providing means for removing the water of condensation, which in the case of long horizontal pipes sometimes assumes a large volume running along the bottom of the pipe. The separator is, therefore, so constructed that it does not throw together the condensed steam and entrained moisture. As shown in Fig. 8, the stream of water is caught by a projection from the cage, and is at once conveyed to the well without being mixed with the steam. The entrained water

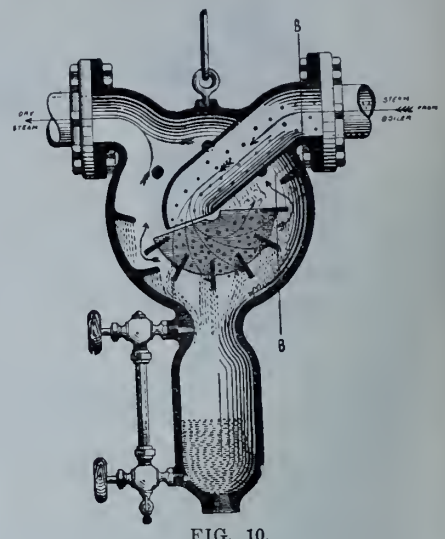

FIG. 10.

goes with the steam around the inner pipe, and is thrown by centrifugal force against the surrounding perforated copper sheet, through which it can readily pass, but through which it cannot return.

In passing around the inner pipe, the shape of the current of steam is changed from a circular to a narrow rectangular one, and is also subjected to a whip-snapping action, which throws off any moisture left in the steam. A metal ring at the bottom of the separating cage prevents the steam from picking up any water from the water chamber.

In the vertical type, Fig. 9, the water coming in with the steam is caught in the upper chamber and carried by the pipe shown to the water chamber, the remaining action being the same as in the horizontal type. These separators are built by the Strong, Carlisle & Hammond Co., Cleveland, O., in sizes from 3 in. to 12 in., both types being built in two sections, the lower one acting simply as a water collecting chamber. When a receiver type of separator is desired, it is furnished of any required dimensions by enlarging the water chamber.

W. & McD. Combine Separator

In these separators, use has been made of four methods of separation; viz., expansion, reverse of current, centrifugal force and baffle plates. These accepted mediums are combined in a suitable manner so as to give desired results in separating entrained water from steam. The steam enters as shown, the increased volume of the chamber reducing the velocity so that the heavier particles fall out by gravity.

By placing the mouth of the inlet pipe in the position shown, the steam is caused to reverse its current, and also assume a whirling movement, the separating effect of which is further enhanced by a series of baffle plates placed in a circular position radiating toward the

centre in the path of the steam. These form an obstructing surface for all non-elastic substances to impinge against and be precipitated to the well of the separator for removal by trap.

These separators are built by Watson & McDaniel Co., Philadelphia, in sizes from 2 in. to 9 in. for a working pressure of 125 lbs. per sq. in., in cast iron. Sizes from 10 in. to 20 in. are built entirely of steel plate.

CHIMNEY AND MECHANICAL DRAUGHT

IN the course of a paper read before the recent annual convention of the American Smoke Prevention Association, E. R. Fish stated that boiler and furnace practice had changed to such an extent that the generally accepted ideas of a few years ago were now largely obsolete. Most large and many small plants were now equipped with mechanical stokers of some one of the numerous types, particularly in those centres where room was limited and smoke abatement laws were enforced. While chimneys alone were still largely depended upon to produce the draught necessary for the combustion of fuel, the tendency was strongly towards supplementing them with mechanical equipment. The effective draught, or that which was used for getting the air through the fuel bed, might be produced in three general ways: First, by the natural draught of the simple chimney; second, by induced draught; third, by forced draught; yet, when the whole of the boiler installation was considered, several combinations of these might be desirable or necessary.

Natural Draught Intensity

Where natural draught alone is depended upon, it must be of sufficient intensity to overcome all the resistances from the top of the stack to the ashpit door. With a given height of stack the available draught was practically fixed, although it varied with the temperature, state of the weather, barometer, etc. A chimney of moderate height could not supply a sufficient draught to maintain what was now looked upon as a high rate of combustion. For conditions under its maximum, natural draught was easily controllable by means of dampers so that the furnace conditions could be maintained at the most economical point. The principal recommendations of a chimney were its simplicity of operation, its need for comparatively little care and attention, and its being always on the job. Its thermal efficacy was low, but the other advantages offset that in cases where high draught intensity was not needed.

To attain a strong draught by means of a chimney was prohibitive because of the great height involved and the cost. It was therefore necessary to turn to other arrangements, such as an induced-draught system, wherein the suction was created by a fan. The nature of this draught was exactly the same as chimney draught, but it had the advantage of being susceptible to accurate control so that the furnace needs might be readily met. It made possible the installation of economizers to lower the temperature of the escaping gases and effected a saving in fuel.

Combination Feature

At the present time a combination of forced draught and either natural or induced draught was being used more and more. Many of the later stokers were operative only with forced draught and were designed for high rates of combustion. Forced draught alone was not a good arrangement for the reason that it created a plenum throughout practically the whole installation and made leaks outwardly through the interstices in the setting likely. By providing a stack of proper height or an induced-draught fan the necessary suction draught might be supplied to overcome the resistance of the gas passages, leaving the forced-draught fan to supply the pressure necessary to overcome the resistance of the fuel bed. This produced that desirable condition, balanced draught, the pressure above the fuel bed being practically zero or preferably a little on the minus side, namely, the draught gauge should show a slight vacuum.

The amount of fuel burned under a boiler largely determined the amount of steam that would be generated. There was, of course, a more or less well-defined relation between grate area and heating surface, although this varied between rather wide limits. The heating surface of boilers in many instances was being worked far harder than was supposed possible a few years ago. This had been brought about by the introduction of furnaces capable of high rates of combustion, with the result that the temperatures of the escaping gases was too high for the proper economy, rendering necessary the use of feed-water economizers of proper capacity.

The need for a high intensity of suction draught in connection with forced draught, when high capacities were used, was not generally recognized. When it was realized that the draught required to cause the flow of gas increased as the square of the velocity, it would be seen that this was important. If ½ in. in the uptake was sufficient for satisfactory operation at one capacity, doubling the capacity at least doubled the quantity of gas, which meant that the gases must flow twice as fast, assuming that the furnace efficiencies and temperatures were the same in both cases. Theoretically, therefore, it would take four times as much draught, or 2 in., as measured by the water column. It was on this rock that many engineers had come to grief in that the attainment of their desire to get a high capacity out of their boilers had not been possible, because after reaching a certain rate of combustion, there was a plenum created in the furnace and through the setting, resulting in furnace gases coming out through the numerous interstices owing to the insufficiency of the available suction draught to pull the gases through the boiler and breeching.

The balanced condition was highly advantageous in another way. The greater the difference in pressure between the inside of the setting and the outside, the greater the amount of air drawn in through any cracks or openings, as well as through the porous setting. The less these differences in pressure the less air would be drawn through. All such air was only detrimental and could do no possible good. Every effort should be made to prevent these leakages if the boiler plant was to be run at its highest efficiency.

The attempt to force a grate to burn more fuel than the draught available inevitably resulted in waste and inefficiency through the formation of carbon monoxide instead of carbon dioxide, so that where draught could not be increased beyond a certain point, care must be used not to force a higher rate of combustion than could be efficiently maintained. Every set of boiler and furnace conditions had its most economical point of operation, which could not be exceeded with satisfactory results, but this was true within much narrower limits of simple chimney draught than with either forced or induced draught with the accompanying possibility of widely varying adjustments.

Tendency of Modern Boiler Practice.

The tendency of modern boiler practice was decidedly toward setting boilers well above the grates so as to give a large combustion space. It was pretty generally recognized that the heat of combustion should all be freed before any of the gases came in contact with the heating surface of the boilers, which, in relation to the gases, was the cooling surface. A large, high furnace and combustion chamber was essential to attain this end, in addition to which the resistance to flow was minimised.

It was important that the breeching should be as short and direct as possible. Square turns of any sort should be avoided, as all such increased the resistance. The well known principles governing the flow of water applied almost as universally to the flow of gases. Easy curves should be provided and all corners and dead spaces avoided. Areas must be properly proportioned to the volume of gases to be cared for, and this was particularly true in those plants where high overload capacities were contemplated.

Modern boiler practice seemed to indicate that for the larger and more important plants, at least, something more than ordinary chimney draught was needed. Where simplicity of installation was paramount, simple chimney draught could not be improved upon. As applying to the average plant throughout the country, every means should be used to prevent air from entering the gas passages other than through the fuel bed, and that the loss of draught due to restricted, improperly designed, and obstructed flues be reduced to a minimum, so that the boiler and furnace would be in condition to give the maximum efficiency.

Progress in New Equipment

SINGLE AND MULTI-STAGE STEAM TURBINES

THE merits of the combination type of steam turbine have met with constantly increasing recognition during the past few years, and the turbine shown herewith has been developed to meet the demand for turbines of that type in sizes from 5 to 1000 horse-power.

The Moore steam turbine is built by the Moore Steam Turbine Corporation, Wellsville, N.Y., in both single-stage and multi-stage designs, the former consisting of a single velocity stage made up of a set of diverging expanding nozzles and a wheel carrying two rows of moving blades, with a set of stationary reversing vanes following the first row of moving blades.

Figs. 2 and 3 are sectional drawings of the single and multi-stage turbines respectively from which it will be observed that the multi-stage turbine consists of the same single turbine, followed by two or more single pressure stages. Each of these single stages consists of a set of nozzles and a wheel. This form of turbine has given very efficient results in large size units, but has not hitherto been built in small sizes because of its rather high cost of construction. To overcome this difficulty, the Moore steam turbine has been so designed and standardized that the different parts can be produced on a quantity production basis; all standard parts are made for stock which enables rapid assembly and shipment of standard machines and also facilitates the supply of spare parts with consequent saving of time in repair.

In order to avoid possible trouble resulting from excessive speeds the designers of these machines have limited the speeds of the larger sizes to 3,600 revs. per min. and of the smaller sizes to 5,000 revs. per min. as a maximum, the required steam consumption being obtained by multi-staging when necessary. By this means the rotation stresses are kept at a low figure with a larger margin of safety. A benefit obtained from the use of a velocity stage for the first stage is, that on account of the comparatively large drop in pressure in the first stage, there is less difficulty in packing the shaft against leakage at the high pressure end of the turbine.

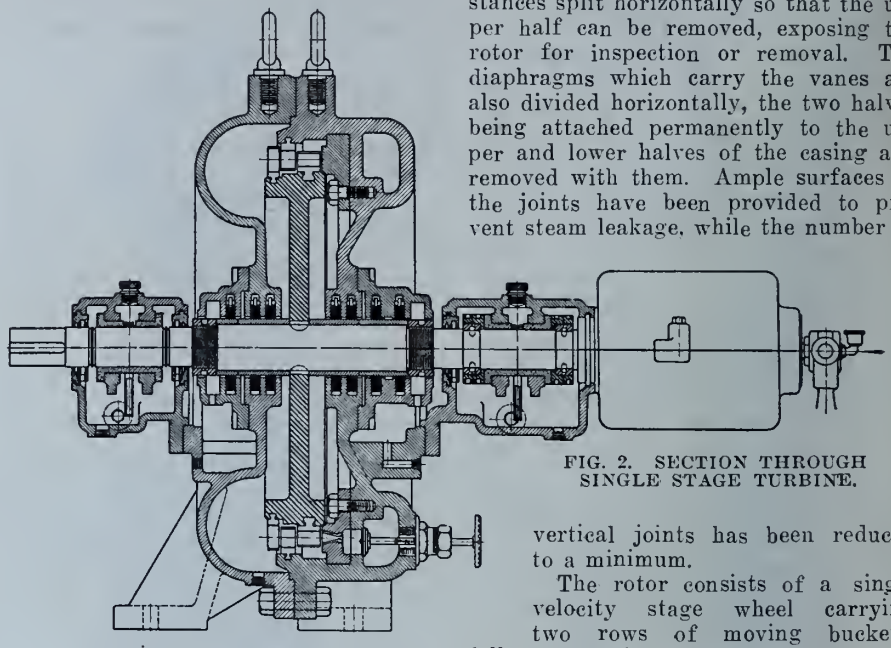

FIG. 2. SECTION THROUGH SINGLE STAGE TURBINE.

The turbine casings are in all instances split horizontally so that the upper half can be removed, exposing the rotor for inspection or removal. The diaphragms which carry the vanes are also divided horizontally, the two halves being attached permanently to the upper and lower halves of the casing and removed with them. Ample surfaces at the joints have been provided to prevent steam leakage, while the number of vertical joints has been reduced to a minimum.

The rotor consists of a single velocity stage wheel carrying two rows of moving buckets, followed by the pressure stage wheels, all mounted on the same shaft.

Drawn steel buckets are set into a dovetailed groove in the periphery of the wheel, being easily removed when renewal is necessary. Liberal clearance (½ in.) is allowed over the ends of the buckets, while the endwise clearance is so arranged that the side of the wheel and not the buckets will rub, should the rotor be displaced lengthwise. The nozzles in the first stage are of the diverging, expanding type and are made of bronze, cast and finished accurately to size, and then recast into a cast iron ring which is attached to the steam end casting. The nozzles of the second and following stages are formed by casting sheet metal strips into the diaphragms, being afterwards broached out to gauge to the size required; this method of manufacture gives a perfectly smooth and highly efficient nozzle.

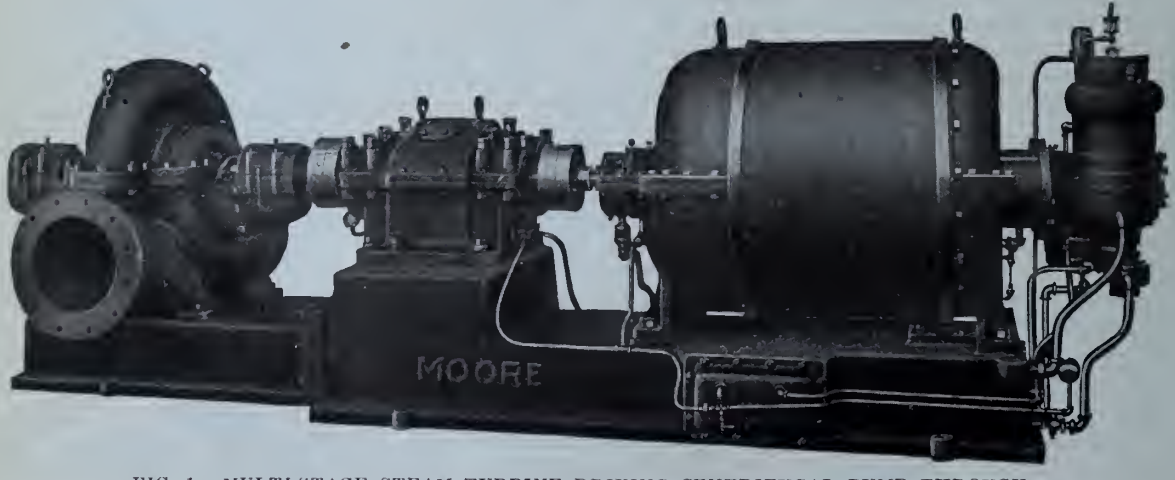

FIG. 1. MULTI-STAGE STEAM TURBINE DRIVING CENTRIFUGAL PUMP THROUGH DOUBLE HELICAL REDUCTION GEARS.

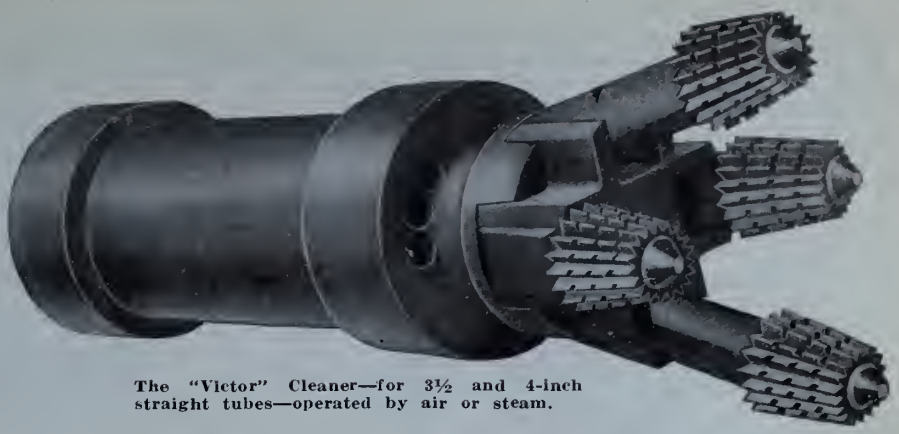

The "Victor" Cleaner—for 3½ and 4-inch straight tubes—operated by air or steam.

THE VICTOR

"The longer it runs, the better it works"

This is what Mr. Christensen, Chief Engineer of the Des Moines Electric Company, said when speaking of a test made in his plant between the Liberty, "Victor" Tube Cleaner and a "best" cleaner of another make. He had purchased both machines, and the test was simply to find out for his own satisfaction which machine was really the best.

He explained that at the beginning of the test it was about "nip and tuck," but when four or five boilers had been cleaned the other machine began to slow up and they were unable to get very satisfactory results. With the "Victor" Cleaner, he continued, the longer it ran the better work it accomplished.

The results of this test emphasize the claim made for the "Victor" Cleaner—that it will do as much or more work, and will last longer than any other cleaner built. These are the things that count when you have a boiler down for cleaning.

You can't afford to have a boiler idle two days for doing a cleaning job that should be done in one; neither can you afford to have the operator spend a half or more of his time making repairs to the tool.

Whether you have forty boilers with heavy scale, or only one boiler with light scale, you will find it economy in the end to use the best tool available, and for operation with air or steam that tool is the "Victor."

No scale can withstand the spurs of "Victor" Tube Cleaners.

Catalogue "H" describes the "Victor" Cleaner. Also the "Bulldog." It's the one to send for if you are interested in getting rid of scale in the easiest and fastest way.

LIBERTY MANUFACTURING CO.

6904 Susquehanna Street - - - Pittsburgh, Pa.

The "Bulldog" Cleaner—the King of all Tube Cleaners—operated by water.

If any advertisement interests you, tear it out now and place with letters to be answered.

Reversing vanes are used only between the two rows of moving buckets of the first stage wheel, being set into a bored dove tail groove in the steam end casting, and held securely in place by suitable attachments.

The bearings, which are of a suitable high speed type are fitted either with

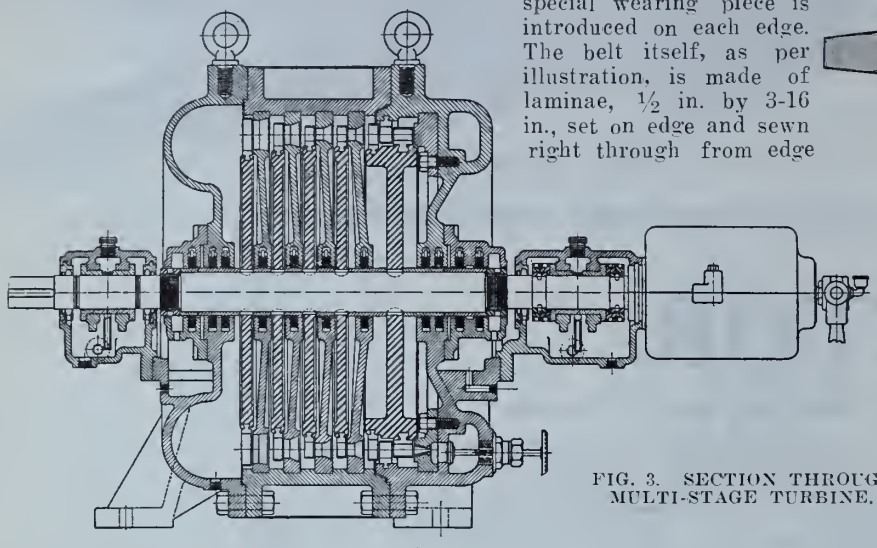

FIG. 3. SECTION THROUGH MULTI-STAGE TURBINE.

ring or forced lubrication, or both, depending on the size of turbine and operating conditions. Suitable thrust bearings are provided to maintain the rotor in its correct operating position. Where extremely close regulation is required, as in the case of generator units, an oil relay governor is fitted, a Jahns governor being used to actuate the oil relay control. For ordinary service, the governor is of the direct connected type mounted on the end of the turbine shaft and actuating a regulating valve of the double beat balanced poppet type. An overspeed governor is provided which is entirely independent of the main governor, and which, should the speed of the turbine exceed a certain predetermined amount, trips a valve in the main steam connection.

Non-condensing turbines in small sizes are usually of the single velocity stage type; and in larger sizes are of the three or five stage multi-stage type; condensing turbines up to 500 horsepower are built as five or seven stage machines. A larger number of stages is used for 500 to 1,000 horse-power machines.

PROTECTION-EDGE LAMINATED BELTING

BELTS on a planing machine are shifted from pulley to pulley every minute,

PROTECTION-EDGE LAMINATED BELTING.

sometimes every few seconds. There is therefore great wear on the edges, due to the friction of the belt forks, and the edges may be worn out while the centre of the belt is still in good condition. The result is that extensive repairs are required, involving delay and expense. To prevent this occurrence, John Tullis & Son, St. Ann's Leather Works, Glasgow, Scotland, have just introduced a protection-edge laminated belt, in which a special wearing piece is introduced on each edge. The belt itself, as per illustration, is made of laminae, ½ in. by 3-16 in., set on edge and sewn right through from edge to edge of the belt, the stitches lying on the neutral axis. The outer lamina on each side is hollowed on its outer face, as shown, and the protection strip is laid in this hollow. This strip is originally 1 in. wide by 3-16 in. thick, and it is laid against the edge of the belt like the flange against the web of an I beam. The stitches pass first through the protection strip, then through all the laminae, and finally through the second protection strip, binding them all firmly together. When the sewing is complete, the protection strip is bent into U-form, as shown, and the two limbs of the U are sewn tightly together, a layer of cement being interposed between them. The protection strip thus becomes flush with both surfaces of the belt, and its outer edge is finally rounded off.

We understand that the belt answers immediately to the touch of the belt-fork and changes pulleys instantly, effecting a marked saving of time. In a recent trial a saving of nine hours per week was registered. As there is no cross-joint, since the joints in the various laminae occur at different places, there is no jolt or jar as the belt passes over the pulley.

TO Professors Ayrton and Perry we owe not only the first ammeters and voltmeters, and the first practical clock meter —revived later as the Aron meter—but a number of improvements in moving-needle and moving-coil galvanometers, and other testing instruments.

MACHINIST'S SCREW DRIVER

A MACHINIST'S screw driver of robust construction has been put on the market by the Peck, Stow & Wilcox Co., Cleveland, O., a feature of which is a special square shank which permits the use of a wrench in turning heavy screws, enabling sufficient pressure to be

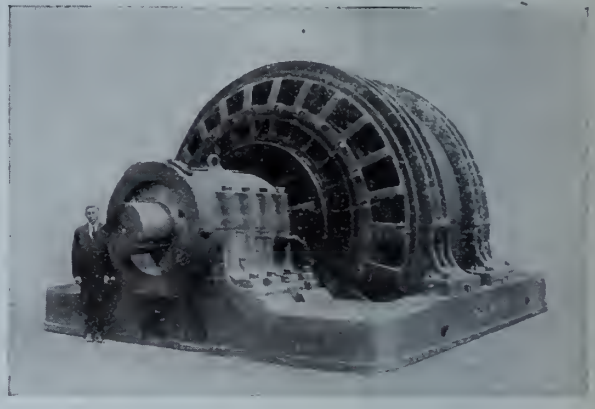
SOLID BAR MACHINISTS' SCREWDRIVER.

brought to move the most stubborn screw.

This No. 1 size screw driver, marketed under the name of Pexto, is of "Solbar" construction, a solid bar of steel forming both shank and handle, and will withstand rough usage under all conditions.

LARGE ELECTRIC MOTOR

MODERN developments in electrical power equipment are aptly illustrated by the accompanying photograph of what is said to be both the largest and most powerful electric motor ever built. The engraving shows it in the shops of the builders, the Westinghouse Electric & Mfg. Co., East Pittsburgh, Pa. It is designed for driving a two-high 35 in. reversing blooming mill which reverses for every pass, i.e. every time metal goes through the rolls.



LARGE ELECTRIC MOTOR.

The horse power developed is 15,000 and reversals can be made from full speed to full speed in about 2 seconds, 19 or 20 passes being made in 2 minutes under regular working conditions. The total weight of the complete motor is over 250 tons, the rotating part alone weighing 100 tons. The overall height is 20 ft., while the shaft diameter exceeds 24 ins.

Marvels of Creation.—A Scotch preacher had been abroad and when he came back he was preaching to his congregation on the marvels he had seen.

He wound up with this: "And the same Creator who made the vast ocean, made the dewdrop. The same Creator who made the mountains made the pebble. Yes, and that same Creator who made me made a daisy!"

The Power You Waste Pays for S K F Bearings

Why waste power? You can save 15 to 24% of your total power consumption. You can increase speed. Save lubricant. Eliminate hot boxes. Reduce fire hazard. Avoid oil-soaked floors and stock. You can have efficient trouble-proof ball bearing hangers at the cost of the power you waste.

S K F Self-Aligning Ball Bearing Hangers on the ball and socket principle, permitting of instantaneous and automatic self-alignment within the bearing itself. The actual savings of others who use S K F will convince you exactly how much you can save. Learn the facts.

If you are having transmission troubles and wasting power needlessly—if you want to have a cleaner, better-looking shop—use S K F.

We will gladly send you complete literature and letters from some of the big S K F users. Ask us to send you the "EVIDENCE."

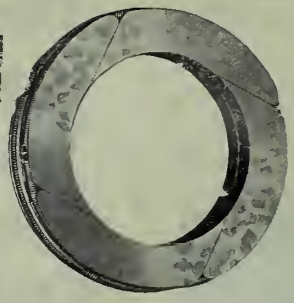
MARTELL PACKINGS MEAN.. MORE POWER



USE MARTELL PACKINGS ONCE AND YOU'LL WANT THEM ALWAYS

They are up-to-the-minute packing service givers.

The secret of their superiority lies in this construction:

They are cut at a tangent to the piston rod and joints on diametrically opposed sides of the piston are parallel. This arrangement of the joints of the ring allows the parts to adjust themselves to every slight inequality of wear in the diameter of the rod as they float freely. Friction and wear upon the rod are practically negligible.

No clearance for wear adjustments need be left between the ends, and sudden failure with this type of packing is impossible. Try them now.

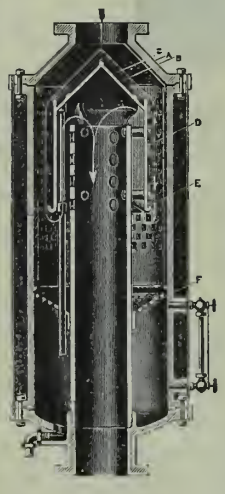
III IMPORTANT THINGS

TO CONSIDER ABOUT A SEPARATOR.



I. **THE PLAN**—Is it sensible, will it work, no matter how large the Separator or how well made?

II. **THE SIZE**—Is it big enough regardless of plan, will it hold a good dose of water?

III. **THE CONSTRUCTION**—Is it strong enough, are flanges heavy, how will it look by the side of a nicely finished engine? Send for catalog and note these points in

LEATHER PACKINGS

The value of any packing depends entirely upon its wearing qualities and power of resistance to destructive agencies.

G & K Leather Packings possess these essential qualities to the highest degree, because they are made in a correct, technical manner from leather exactly suited to the conditions under which the packings are to be used.

There are G & K Leather Packings for all ordinary requirements, there are also G & K Leather Packings which will resist to a greater degree than any other packings exposure to heat, hot or cold water, gas or acid fumes, oil, steam or other adverse conditions.

In short, for any service and every service, G & K Leather Packings mean better packing service to-day, to-morrow, and years from to-morrow.

Our Packing samples, prices and literature should interest you.

No Expansion Trouble

ALBERGER Multi-Head Heater

An apparatus that's full of superior features.

BE SURE TO READ THIS

One feature is the **Double Floating Head**—a construction that eliminates the dangers of expansion strains to which other heaters are subjected. The movable or floating heads are in sections, so as to differentiate between the expanding and contracting of the tubes of **different** temperatures.

Another is the **COPPER Corrugated** Tubes. This eliminates the segregation of materials, and splitting, so common with brass tubes. The helical spiral corrugation gives the water a whirl, which keeps the **tubes clean and free from scale.**

INCREASES HEAT UNITS BY 50% OVER THE STRAIGHT TUBES SO COMMONLY USED.

It will pay you to learn more about the "ALBERGER" Multi-Head. Send for new descriptive circular to-day.

MACLEAN'S MAGAZINE *for* March

Sir Gilbert Parker
Robert W. Service
Stephen Leacock
Alan Sullivan
Agnes C. Laut
H. F. Gadsby
Erman J. Ridgeway
Madge MacBeth
L. M. Montgomery
Norman Lambert
Hopkins Moorhouse
H. M. Tandy
Robson Black
Adam Barnhart Brown
Arthur William Brown
Peter McArthur

BE thankful that Canada has a magazine of BIG calibre. A magazine fit to be placed alongside the best British and American magazines—by the test of those who contribute to it regularly and of ideals.

MACLEAN'S MAGAZINE carries world-famous names in its list of contributors—writers who have an open sesame to any magazine, yet writers that some magazines cannot get, because they fail to measure up to a standard set. Not every or any magazine can have the work of Sir Gilbert Parker, Miss Laut, Stephen Leacock, Arthur Stringer, Arthur E. McFarlane, L. M. Montgomery, Nellie McClung, Robert W. Service, Alan Sullivan, and others whose names are familiar to readers of MACLEAN'S MAGAZINE.

MACLEAN'S MAGAZINE is favored by these fine and high-priced writers because they are Canadian-born or bred and because they are genuinely interested in seeing the land of their birth or adoption have a magazine worthy of the land of their love and of their work and fame. *And they have found this magazine in MACLEAN'S.* MacLean's gives them access to the readership they desire to reach—the man and women of culture and position, of real love for Canada and in earnest to see its nationality enlarge and its destiny advanced.

And so we feel that we have a right to ask you to give MACLEAN'S MAGAZINE a first place in your favor. *It is truly Canadian,* doing a needed service for Canada, and doing this worthily. Doing all that it is doing at a heavy present cost, looking to the future for its larger reward.

You can show your appreciation of what the publishers of MACLEAN'S MAGAZINE are doing by making MACLEAN'S an elect magazine among all magazines enjoying your favor, and by making it better known to others who have your spirit—your sense of Canadian nationality, your purpose to advance Canada in all right and high ways.

Contents of MARCH MACLEAN'S
(CONDENSED)

Jordan is a Hard Road. Serial by Sir Gilbert Parker.

The Guile of Ulysses. By Peter McArthur.

Face Up. By Hopkins Moorhouse.

The Rabbit Revolution. By Adam Barnhart Brown, with illustrations by his brother, Arthur William Brown.

The Above are Stories

Ten Million for the Asking. By Stephen Leacock—a serious contribution on a phase of national finance.

National Policies—How they are formulated and exploited by Parties and Cabinets. By H. F. Gadsby.

Prospects for Peace and Peace's Problems. By Agnes C. Laut. A stirring and thought-provoking article by this wonderful woman writer with a statesman's mind.

The Above are Special Articles

Mrs. Hayter Reed—the woman who is responsible for the decorative schemes of the big C.P.R. hotels. By Madge MacBeth.

H. C. Brewster—Premier of British Columbia. By Norman Lambert. A timely sketch of a man of interest to all Canadians.
These are brief biographies of interesting Canadians—a feature of every issue of MACLEAN'S MAGAZINE.

The Review of Reviews Department condenses for busy readers the cream of the best things appearing in the current magazines of the world. So MACLEAN'S becomes many magazines in one.

The Business Outlook and Information for Investors are two features of MACLEAN'S greatly liked and esteemed by many of its readers.

These are Department Features found in every issue

Projects and Developments

Fergus, Ont.—Beatty Bros. are buying power house and foundry equipment.

Winnipeg, Man.—The Board of the General Hospital is considering building a power plant.

Strathroy, Ont.—The Town Council contemplate purchasing a motor driven turbine pump.

Winnipeg, Man.—The Swift Canadian Co., are considering the erection of an abattoir, to cost $3,000,000.

Cayuga, Ont.—Extensions to the waterworks system are contemplated and will include pumps, cast iron pipe, water tank, etc.

Brantford, Ont.—Fire Chief Lewis has recommended the purchase of a motor tractor for an aerial truck and a new gasoline motor pump.

Toronto, Ont.—The Deyo Macey Engine Co., Binghampton, N.Y., will establish a plant in Toronto for the manufacture of gas engines.

Tecumseh, Ont.—The Eau Claire Waterworks Co., are in the market for two centrifugal pumps and motors. R. W. Code, Windsor, Ont., is the engineer.

Chatham, Ont.—The City Council has closed a deal with the Libby packing house of Chicago to open a branch here, the city giving land for a $100,000 plant.

The Murphy Iron Works, Detroit, Mich., have been awarded a contract by the British Cordite Co. for the 400 h.p. smokeless furnace units to be installed at Nobel, Ont.

Hamilton, Ont.—The Canadian-Desmond-Stephen Mfg. Co., Urbana, Ohio, is making preparations for the erection of a plant here for the manufacture of steam ejectors, etc.

B. G. Michel, recently engineer for Carleton Place, Ont., has opened offices in the Bank of Toronto Building, Kitchener, Ont., for consulting practice in civil and sanitary engineering.

Winnipeg, Man.—The Greater Winnipeg Water District Board has authorized the commissioners to call tenders for cast iron pipes, valves and specials for the pipe line between the Red River and McPhillipps Street reservoir. The estimated cost is about $250,000.

Niagara Falls, Ont.—The Hydro-Electric Power Commission are buying a large quantity of contractors' plant in connection with their Chippewa Creek development here, including rubber belting, motors, cement, conveyors, electric hoists, derricks, locomotive cranes, small jaw crushers, concrete mixers and machinery, etc.

Toronto, Ont.—Tenders addressed to the chairman of the Toronto Electric Commissioners will be received until March 28, for synchronous condensers. Specifications may be obtained at the office of the Purchasing Agent, 15 Wilton Ave., Toronto.

The Canadian SKF Co. has opened an office at 47 King Street West, Toronto, where a complete stock of ball bearings will be carried. The Canadian Fairbanks Morse Co., will continue as sales agents for transmission equipment made by the parent concern at Hartford, Conn.

Water Purification Ltd., has been incorporated at Ottawa with a capital of $40,000 to manufacture and deal in water purification and filtration plants at Ottawa, Ont. The incorporators are E. M. Knight, J. T. Mitchell and W. A. Wyman all of Ottawa.

The Albany Pump Co. has equipped a plant at 16 Pearl street, Toronto, for making the "Albany" rotary pump and munitions gauges. A. W. Bennet, who is proprietor and manager of the concern, formerly carried on business at 206 King street west, Toronto, as Canadian agent for the "Albany" pump.

Kerry & Chace, Ltd., engineers confederation Life Building, Toronto, are interested in liquid chlorine apparatus and will be glad to receive literature on any plants of proved merit. This firm will be in the market at a later date for plants of this type.

The Canadian S K F Co., has now been incorporated at Ottawa with a capital of $50,000 to manufacture and sell ball bearings and machinery at Toronto. The incorporators are Allan H. MacCaffray of Hartford Conn., also Percy O. G. Jones and James D. Becking of Toronto.

Winnipeg, Man.—The Greater Winnipeg District Board has decided to award the contract for the construction of ten miles of pipe line, at a cost of $1,300,000, to the Winnipeg Aqueduct Construction Co. The matter, however, has not been finally settled, as other contractors have raised objections over the award.

Frank Gilbert a well known engineer died at his home in Montreal on Jan. 23, after a long illness. Mr. Gilbert was born in Montreal in 1847. After graduating at McGill University, he started in 1870 in the foundry business, later joining the firm of E. E. Gilbert & Sons, engineers and contractors. The deceased took an active part in the construction of the Lachine Canal and also of the Galops Canal. Mr. Gilbert founded the old Canadian Engine Works.

The George T. Ladd Co., Pittsburgh, Pa., announce that the name of what was originally the "Milne" boiler has been changed to the "Ladd" water tube boiler. The change has been made on account of improvement in design affecting the settings, feed boxes and other details to the extent that the majority of the patents which the company are utilizing have been taken out by George T. Ladd, president of the company.

Paul J. Myler has been appointed president of the Canadian Westinghouse Co., Hamilton, Ont. For a long time Mr. Myler was vice-president and general manager, but relinquished the duties of general manager some time ago. **F. A. Merrick** has been appointed vice-president and general manager. **H. H. Westinghouse,** the former president of the company, has been appointed to the position of chairman of the board, a new position which has been created.

C. S. C. E. Elect Officers.—The newly elected members of Council are J. S. Dennis, Montreal, president; J. M. R. Fairburn, Montreal and C. N. Montserrat, Montreal, vice-presidents; and A. R. Decary, of Quebec, J. H. Kennedy, of Vancouver, H. Longley, of St. John, N.B., G. A. McCarthy, of Toronto, W. Pearce, of Calgary, R. A. Ross, of Montreal, J. C. Smith, of Montreal and James White, of Ottawa, Councillors

The Sterling Engine Works have taken over the plant and business of the Doty Engine Works, Winnipeg, with works and office at the foot of Water Street. While it is their intention to manufacture farm tractors as a specialty, they will also make boilers, steam and gasoline engines, iron and brass castings, cut gears, for which their plant is specially equipped, as well as general repair work. The president of the new company is V. C. Maddock, the secretary-treasurer F. Nilan, and W. J. Leaney is manager.

Hamilton, Ont—Tenders will be received by the Board of Control up to March 5, for the supply of ordinary asd special castings, iron pipe, hydrants, valves, extension boxes. Lead pipe—Pig lead, rubber hose, rubber boots, road oil, lubricating oil, flux, fuel oil, coal oil, gasoline, brass work, including ordinary and special brass castings for water department, hardware, etc. Specifications may be obtained at the office of E. R. Gray, City Engineer.

Booklet 222T. tells all about it.

Made in JERSEY CITY, N.J., by the
Joseph Dixon Crucible Company
Established 1827

Canadian Representative:
Canadian Asbestos Co.,
Montreal, Que.

Toronto, Ont.—Tenders will be received, addressed to the Chairman, Board of Control, City Hall, up to Feb. 27,, for the construction of a drainage system (wrought iron pipe), for the Rosedale bridge, Bloor Street Viaduct. Specifications and forms of tender may be obtained upon application at the Bloor Street Viaduct field office, 89 Castle Frank Road, Toronto.

Winnipeg, Man.—Tenders will be received up to March 15, by R. D. Waugh, Chairman of Commissioners, Greater Winnipeg Water District, for the supply of approximately 12,500 feet of 48-in. and 1,300 feet of 60-in. cast iron pipes, together with specials and gate valves. Specifications on application to the offices of the District, 501 Tribune Building, Winnipeg.

CATALOGUES

The Valve Twins is the title of a bulletin being distributed by the Homestead Valve Mfg. Co., Homestead, Pa., illustrating the "Hovalco-Homestead" blow-off combination valve.

Boiler Feed Pumps.—The G. H. Tod Co., Ltd., have issued a bulletin illustrating and describing the Tod-Attwood patent vertical ram boiler feed pumps, The principal features of this pump are dealt with in detail, while a table is included giving the principal dimensions and other particulars for each size.

Firebrick Blocks.—A new bulletin dealing with the "Gates" firebrick blocks has been issued by John W. Gates, Montreal. The application of these firebrick blocks is shown by means of a number of illustrations accompanied by descriptive matter. The bulletin describes all types of blocks now being used largely in place of ordinary firebrick.

Steam Traps.—Bulletin No. 5 describes an interesting line of steam traps, made by the Geo. W. Cole Co., Toronto. The principal features of the "Cole" direct return trap are dealt with while the essential particulars and prices are given covering the various sizes. The bulletin is illustrated and includes a diagram showing a double trap installation with a table of fuel losses.

Sub-Aqueous Lubrication, Bulletin issued by the Crew Levick Co., Philadelphia, Pa., dealing with sub-aqueous or under-water lubrication in hydro-electric stations with special reference to hydro-turbine lubrication at McCall's Ferry, Pa. The preparations described are "Turboglio" for under-water lubrication and "hydroglio" for governor lubrication.

Belt Sewing Machine—Bulletin illustrating and describing a wire belt sewing machine made by Joseph Appleyard, Bradford, Yorks, England. Each type of machine for sewing various sizes of belts is illustrated and described, the principal dimensions and shipping weight being given for each size. One page contains a number of illustrations showing the different classes and thicknesses of machine belting which these machines will sew. A large number of testimonials are included from users in various parts of the world.

Nonpareil High Pressure covering for heated surfaces is the title of an interesting and attractive publication recently issued by the Armstrong Cork Co., Pittsburgh, Pa. The booklet contains 84 pages and deals fully with the subject of insulation for high pressure and superheated steam lines, boilers, breechings, feed water heaters, etc. An interesting feature is a list of comparative tests made at the company's Beaver Falls factory, as a result of which they have been able to fix definitely the heat losses from various sizes of pipe both covered and uncovered. These losses are given in B.T.U. per lineal foot, per degree difference in temperature for twenty-four hours and are tabulated. In the following pages are tables which show in a general way, the most economical thickness of "Nonpareil" high pressure covering to use, based on different steam costs. A complete set of specifications is also included dealing with the correct installation of these various thicknesses of covering. The booklet is fully illustrated and is exceptionally well gotten up. It contains a great deal of interesting and useful information. Copies may be had on request by interested readers.

BOOK REVIEW

Steam Boilers and Combustion, by John Batey. 220 pages, 4⅜ in. x 7¼ in., with 18 diagrams. Published by Scott, Greenwood & Son, London, England. Price $1.25, post free. This volume is the fifteenth of the Broadway Series of Engineering Handbooks. In this book the author has striven to deal with the subject in a somewhat different manner than that usually found in works on this subject. Problems of combustion are examined and as far as possible cause is traced back from effect, the causes being referred to well known facts as a comparison. Although the application of certain principles is sometimes questioned, they are accepted as a whole. All analysis is based on recognized science and results compared with authorized deductions. The book contains an introduction and seventeen chapters, dealing successively with various subjects, such as combustion and steam production, principal constructional features of various types of steam boiler, steam boiler practice, temperature, etc. This briefly covers chapters one to twelve, inclusive. The principal subjects dealt with in the concluding chapters include lessons taught by experiment, Philadelphian exhibition lists, normal results obtained by abnormal methods, analysis of actual performance of a locomotive boiler and lastly, movement of gases through tubes. The book, while being in a measure technical, is clear and concise, and contains much valuable information on

NON-FLUID OIL

Not affected by heat or cold. Temperature Proof

Among other sterling qualities and advantages of NON-FLUID OIL, the quality of being **temperature proof** is a great convenience and makes a big saving in time and in the cost of running operations.

Where extremes of temperature are experienced NON-FLUID OIL may be used to great advantage.

NON-FLUID OIL operates with equal readiness summer or winter, outdoors or near the boilers.

Applied in every bearing from the engine to the hauling up and cantering machinery, Non-Fluid Oil will save enough fuel and repairs in a year to buy lubricants for ten years. There is no loss from dripping and fire risk is minimized. High speed bearings run perceptibly cooler and are longer lived.

We strongly advise a long, accurate test of the claims we have made for these lubricants. Samples for the purpose will be gladly furnished free on request. Ask for literature giving full particulars.

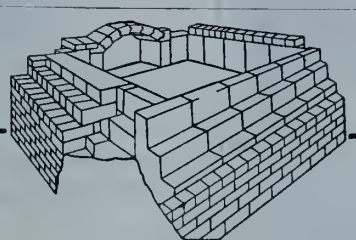
a phase of boiler operation which is frequently not given the attention that its importance merits. In addition to the diagrams, the book contains a number of tables and some useful rules and examples.

Heaton's Annual, Heaton's Agency, Toronto, price $1 net. The thirteenth edition of Heaton's Annual has just come from the press, and again we have to note improvements and refinements which have marked its progress from year to year. Heaton's Annual endures because recognized as a necessity both in the office and the home. Indeed, to financial or commercial houses in Canada or abroad and who do business with Canada, the book is indispensable, the expression, "Look it up in Heaton's," having become a habit in many households. The first part of the book contains complete official directories of the Dominion and Provincial Governments, to which is added this year a long list of titled and decorated Canadians that will be of interest to many families who have boys at the front; also postal information; a shipper's guide, giving every banking town, with banks and railway connections, population, etc.; commercial regulations and complete customs tariff revised to date. In the last half of the book we find up-to-date complete descriptions of every commercial town in Canada with hotels, industries, population and industrial opportunities, and an invaluable and complete summary of the resources of the Dominion, covering agriculture, agricultural districts, finance, fisheries, forests, fur farming, mining, sport, water powers, etc. The information is full, live, clearly arranged and concisely stated. Cross references are given throughout the text to a most valuable bibliography of Government and standard publications under the heading, "Where to Find It," so that the reader has access to complete information upon any subject in which he is interested.



Gates Boiler Furnace

Patent Applied For

Will last three times as long as ordinary good grade Fire Brick. These blocks are inter-locking, and made so that any bandy man or fireman can renew them without disturbing any of the other brick work.

—WRITE FOR PARTICULARS—

John W. Gates, 382 St. James St., Montreal, Que.

Do You Know Why The Steam Trap SARCO

Is used by nearly all the big industrial concerns?

THIS IS WHY

The Steam Trap SARCO is operated by the expansion of a liquid operating a spirally corrugated tube. There is no other steam trap made which uses liquid expansion and none can use this enormously powerful and reliable operating medium without using also the Sarco tube. Therefore of all thermostatic traps the SARCO claims to be the most positive—and it can be supplied not only for vacuum heating systems but for low pressure and high pressure steam up to 200 lbs. Do you know any other thermostatic trap used successfully for pressures above 50 lbs. or even as high.

Then as to installation. The SARCO fits in anywhere. (1" size measures only 7½"); it needs no floor space or building up, but can be used as an elbow or bend, in the discharge. Although it does just the same work, it is not a heavy, cumbersome affair like a float or bucket trap. It is not a tank, but a piece of live pipe. It cannot freeze and will not permit freezing of the pipe line. Unless steam is in the line the trap is wide open to discharge.

Price—it is the cheapest trap on the market in first cost—cost of installation and cost of upkeep.

Take a trap on thirty days' trial and prove this for yourself.

Write for Bulletin 11.

NOTICE

TO

Stationary and Hoisting Engineers

Everyone operating a STATIONARY steam plant of 50 h.p. or over in the Province of Ontario must hold a Stationary Engineer's Certificate from the Board of Stationary and Hoisting Engineers. Anyone operating such a plant without a Certificate is liable to the penalties set forth in the Stationary and Hoisting Engineers' Act.

Everyone operating a HOISTING steam plant working at a pressure of 20 pounds or over, irrespective of horse power, and used for hoisting in structural operations or excavating purposes, in the Province of Ontario, must hold a Hoisting Engineer's Certificate from the Board of Stationary and Hoisting Engineers. Anyone operating such a plant without a Certificate is liable to the penalties set forth in the Stationary and Hoisting Engineers' Act.

Application forms for obtaining STATIONARY or HOISTING Engineers' Certificates, may be had upon applying to the Chairman.

HON. F. G. MACDIARMID, Minister of Public Works and Highways. W. C. McGHIE, Chairman of Board.

McDANIEL IMPROVED STEAM TRAP

FOR HIGH OR LOW PRESSURE.

Steam can't blow through. They have large discharge valves and cannot be flooded from sudden flushes of water.

MAY WE SEND ONE FOR TRIAL?

Reducing Valves, Pump Governors, Relief Valves, Exhaust Pipe Heads, Ejectors and Steam Separators.

SEND FOR CATALOGUE.

Hawkins' Aids
Free to Engineers

This work is an important aid to engineers of all grades, and is undoubtedly the most helpful ever issued relating to a safe and sure preparation for examination. It presents in a condensed form the most approved practice in the care and management of Steam Boilers, Engines, Pumps, Electrical and Refrigerating Machines, also a few plain rules of arithmetic with examples of how to work the problems relating to the safety valve, strength of boilers and horse power of the Steam Engine and Steam Boiler.

It contains various rules, regulation and laws of large cities for the examination of boilers and the licensing of engineers.

The book gives the underlying principles of steam engineering in plain language, with very many sample questions and answers likely to be asked by the examiner.

It also gives a short chapter on the "Key to Success" in obtaining knowledge necessary for advancement in engineering.

This helpful volume contains 200 pages of valuable information not elsewhere obtainable; it is bound in rich red leather with full gold edges and titles; it measures 5x7½ inches, and weighs twenty-two ounces.

Price, $2. Free for 3 NEW prepaid subscriptions to The Power House.

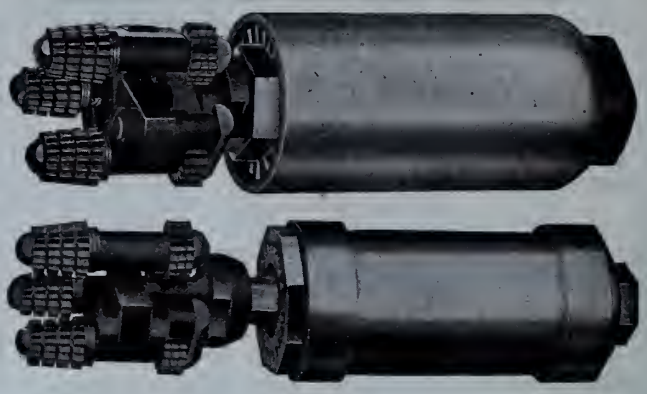
BABCOCK & WILCOX LIMITED

LAGONDA
BOILER TUBE CLEANERS

The latest Lagonda Water and Air-Driven Boiler Tube Cleaners are the most powerful and efficient tube cleaners made. They develop higher speed and greater power than has heretofore been secured with any Turbine Cleaner, and their use will materially shorten the time required in cleaning boilers.

These new Lagonda Cleaners are built for all sizes of tubes, either straight or curved, and they can be driven by water, air or steam.

Ask for Catalog L.



LAGONDA Multiple Water Strainers

The Lagonda Multiple Water Strainer in your water supply main will remove all objectionable solid matter and insure constant and economic conditions of pump and condenser operation. They are easily and quickly cleaned, without interruption of water supply, and take up small floor space. **Ask for Catalog R-2.**

H&M Thermometers

Guides to Efficiency

The high efficiency of your Plant cannot be maintained without an accurate knowledge of the steam and water temperatures and pressures.

H&M *Tycos* THERMOMETERS

are precise in their readings. Mounted in heavy frame with separable socket,- either straight or angle type.

Let us help you select the right thermometer for your conditions. Write us to-day.

We are manufacturers of H&M Type Angle and Straight Stem Thermometers, Automatic Temperature and Pressure Regulators, Mercury Vacuum and Absolute Pressure Gauges, Engraved Stem Thermometers, Hydrometers, Hygrometers, Thermo-Electric and Radiation Pyrometers.

UEHLING WASTE METER

COMBINED

CO_2 AND TEMPERATURE RECORDER

Record of CO_2 and stack temperature on one chart.

Does your fireman know how much fuel he is wasting? Do you know?

The **Uehling CO_2 Recorder** makes a complete 24 hr. record of your combustion efficiency and the **CO_2 indicator at the Boiler Front** holds the fireman responsible.

Get more **Steam** per pound of **Coal** and reduce your annual fuel consumption.

Let us know the number and size of your boilers and coal consumed per year, upon receipt of which information we will be glad to send you full particulars.

CO_2 Indicator for Boiler Front

Let us hear from you. We are pioneers in the manufacture of Indicators and Recorders for Power Plant purposes.

Send for our Bulletin No. 110.

Uehling Instrument Company

2008 Empire Building New York City

BOILER ACCESSORIES

By Walter S. Leland, S. B.

Formerly Assistant Professor of Naval Architecture, Mass. Institute of Technology, American Society Naval Architects and Marine Engineers. 144 pp., 72 illus. Cloth binding. A treatise giving complete descriptions of the various accessories of the boiler room and engine room essential to economical operation, such as evaporators, pumps, feed-water heaters, injectors, mechanical stokers, etc., with practical instruction in their use. **Price** $1.00

STEAM TURBINES

By Walter S. Leland, S. B.

Assistant Professor of Naval Architecture, Massachusetts Institute of Technology, American Society of Naval Architects and Marine Engineers. 160 pp. 100 illus. Cloth binding. A reliable and up-to-date manual on the selection, construction, and operation of steam turbines, including the installation, performance and types of turbines; single-stage and compound turbines, such as De Laval, Riedler-Stumpf, Rateau, Hamilton-Holswarth, Terry, Parsons, Allis-Chalmers, etc., with a discussion of the use of low-pressure steam turbines with steam engines. **Price** $1.00

Write TECHNICAL BOOK DEPARTMENT

THE MACLEAN PUBLISHING COMPANY

143-153 University Avenue TORONTO

Scarcely Any Depreciation
Indefinitely Long-Lived
Practically No Maintenance Cost

And besides—the

SPRACO Cooling System

can be installed for less than a cooling tower will cost. Operating power averages less than 1½% of power generated by engine (average cooling tower requires 3%). Average vacuum the year round of 28″ may be secured.

Installations on the ground or roof. Almost any ordinary roof will do, as very little weight is carried on the roof.

"Spraco" costs soon come back.

We install systems complete to individual requirements.

Write us your needs and for full particulars.

Don't buy that New Electrical Apparatus Just Yet

WE can supply you with high-grade apparatus that has been slightly used and discarded through no fault of its own, at an **immense saving in cost.** For instance, in many cases we take over entire plants simply because of changed conditions such as increased capacity, change of system, etc.

EVERYTHING IS OVERHAULED AND REFINISHED BY US AND **GUARANTEED** AS GOOD AS NEW, BOTH ELECTRICALLY AND MECHANICALLY.

Our catalogs of offerings should be in the hands of every power plant superintendent each time they are gotten out, and it will be worth while for anyone interested in this class of power plant equipment to be on our mailing list to receive all offerings.

Nearly all of the principal power, lighting and street railway plants in the United States are our customers.

WRITE FOR OUR LATEST CATALOG of **Power House Equipment, Street Cars, Motors, Hoists, Compressors, etc.**

MACGOVERN & COMPANY, Inc.

114 Liberty St., New York City

The Wrench of 25% Greater Efficiency

TRIMO PIPE WRENCH

Two new features have been recently added to the Trimo Pipe Wrench, namely Nut-Guards, in all sizes, and unbreakable steel frames, in leading sizes.

The Nut-Guards prevent the accidental rotation of the nut while in use.

These improvements add 25% to the usefulness of the tool.

The Trimo Pipe Wrench is made with wood handles in 4 sizes, 6-in., 8-in., 10-in., 14-in. and in steel handles in all sizes, 6-in. to 48-in. inclusive.

All Trimo Pipe Wrench parts are interchangeable.

The inserted jaw in the handle can be readily replaced when worn, thus adding to the life of the tool.

Nut with Nut-Guards

Inquiries from Importers and Dealers Solicited. Send for Catalogue No. 55.

Representative Installation of Bowser Oil Filtering and Circulating System.

BOWSER ESTABLISHED 1885

When making an important purchase you endeavor to secure the most for the amount expended. Before it is possible for you to be sure of this point, however, it is necessary for you to take into consideration the element of Quality.

Back of the name BOWSER stands an unquestioned reputation, not only for highest quality in material and workmanship, but also in service. This exceptional degree of quality insures a profitable investment to purchasers of Bowser Oil Filtering and Circulating Systems and Oil Handling Devices.

THE POWER HOUSE 143 University Ave., **Toronto**

A Well-Insured Plant

is the power plant of the Ft. Worth Light, Heat and Power Co., Texas. On the inside the coal is stored above the boilers in a Brownhoist Concrete Bin, which time has proved will last as long as the plant and require no repairs. The coal is unloaded on the outside by a Brownhoist Locomotive Crane, which takes it from the cars and places it in storage or puts it through the roof into the Brownhoist Bin. It is safe to say that this plant will have very little trouble, if any, with its coal handling apparatus.

BROWNHOIST

Concrete Coal Bin and Coal Handling Machinery

Write for Catalog S

The Brownhoist Concrete Bin is a steel bin, lined inside and out with concrete. This protects all steel from the corrosive action of the coal or ashes. The oldest one of these bins has been in continuous service for 14 years and has required no repairs. Brownhoist Coal Handling Machines are of various types and sizes for safe, rapid and economical handling of coal. These machines and the bin are described and shown in Catalog S.

CURTIS

Engineering Specialties

CURTIS Water Pressure Regulator

The Economy of this Curtis Water Pressure Regulator (See Illustration) lies in the fact that it greatly reduces the cost of keeping plumbing in order—This by obviating the wear and tear of water hammer or concussion in pipes.

This regulator is warranted to maintain the pressure desired, **with perfect uniformity, regardless of any fluctuations of outside pressure.** The workmanship and material of the Regulator **cannot be excelled.** Trouble from rust or clogging is **entirely avoided.** Delivery of water into service pipes at any desired pressure **is guaranteed.**

Send for special leaflet and price list to the manufacturers.

JULIAN D'ESTE COMPANY

26 Canal Street, BOSTON, MASS.

Engineers with long experience will tell you that

Homestead Guaranteed Valves

are the best for all Water, Air or Steam Lines

Simple in construction, easy to operate, and the only valve which will successfully stand up under the heaviest duty service. Made in Straightway, Threeway and Fourway patterns. Special valves for special purposes.

There's a Homestead Valve for every purpose.

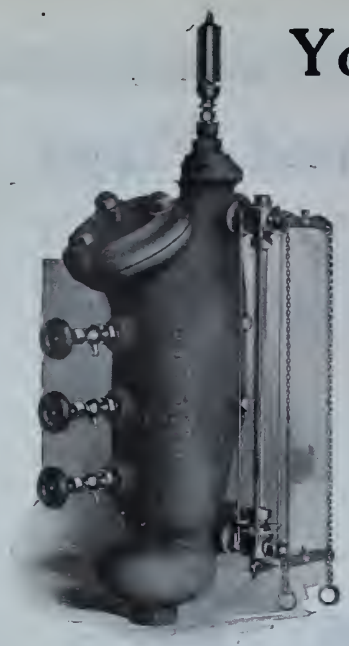
HOMESTEAD VALVE MFG. CO.

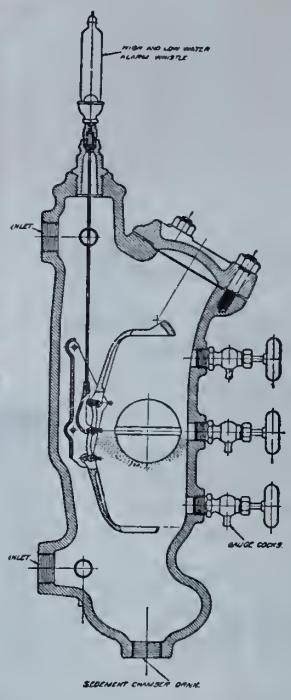
PITTSBURGH - - PENNA.

Works: Homestead, Penna.

Our new circular, describing the Homestead in detail, is ready for you. Drop a card to-day for your copy.

If any advertisement interests you, tear it out now and place with letters to be answered.





You will be given a warning whistle

the instant the water in your boilers falls below or rises above the danger point if you equip your boilers with the

Anderson Safety Water Column

It never fails. Always ready for action when the need calls.

The entire mechanism is assembled as a single unit, a removable hanger frame, and hung on accurately machined bronze pivots. The working parts cannot rust or stick.

Write for catalog and full details.

J. M. T.
Reducing Valves

NON-EQUALIZING
EXTREMELY SENSITIVE
EQUALLY SUITABLE FOR STEAM OR AIR
REDUCING VALVE PERFECTION

The Non-Equalizing feature of the J.M.T. Standard Reducing Valves will surely commend itself to you. A guarantee of a perfectly uniform and dependable service, is remarkably sensitive for control, and is really a long step in advance of Reducing Valve construction.

Made in bronze, ½ in. to 2 in., and iron body, bronze mounted, 2½ in. to 6 in., for various steam ranges between ½ lb. and 300 lbs.

The J.M.T. Improved Automatic Injector

An Injector having a full forty pounds more field than anything heretofore produced and giving absolute service under varying conditions.

A culmination of valuable experience in design and the making of Injectors, likewise increasing the use for Injectors. Will operate successfully on 20 lbs. low to 220 lbs. high steam pressure, from 4 to 400 horse-power, and made in sizes from ⅜-in. to 2-in.

Central Station Economy In Your Own Power Plant

WATEROUS HIGH SPEED McEWEN ENGINES

These engines are built specially for use in the isolated plant. High speed and close regulation recommend them for electric light and power production, mill work and general industrial purposes.

Closeness and speed in regulation are their outstanding features. No difficulty is experienced in adjusting McEwen Engines to govern within the limit of one revolution and the instantaneous variation in speed when full load is thrown on or off is usually less than 2%.

Ability to absorb overload, low maintenance cost, simplicity of operation and great strength of all parts are outstanding features of the McEwen.

In hundreds of Canadian power plants producing their own power you will find McEwen Engines in use. They are in operation because they are developing power that is not only cheap but absolutely reliable as well.

McEwen Engines are built for continuous duty — there are no shut downs because something has gone wrong on the transmission line.

Built in simple and compound units up to 700 H.P. capacity.
May we send bulletin and list of Canadian users?

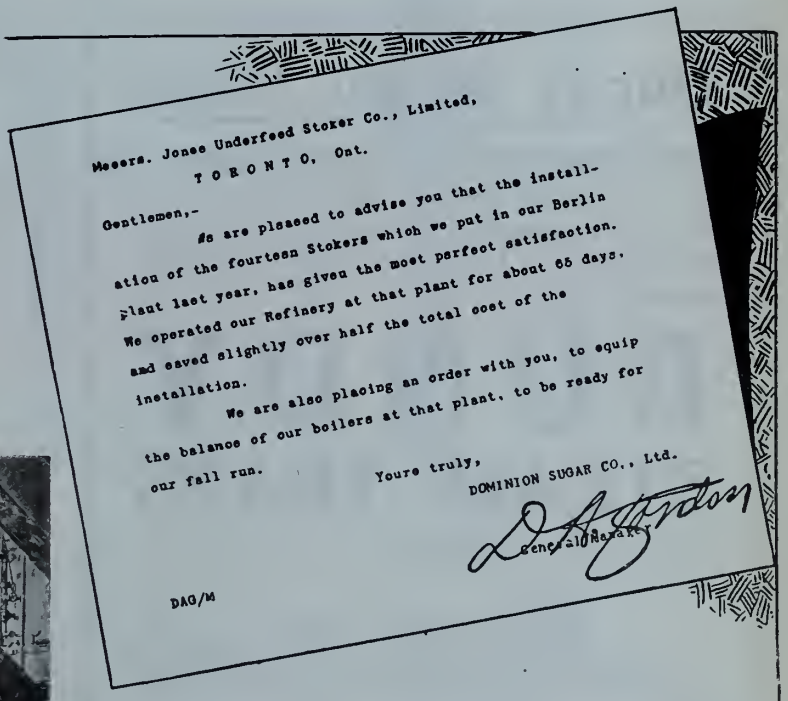
Jones Underfeed Stokers make big savings—

The installation as illustrated below (14 Stokers) has paid over half its cost in 65 days.

READ THE LETTER

DOMINION SUGAR CO., LTD., KITCHENER, ONT.



Messrs. Jones Underfeed Stoker Co., Limited,
TORONTO, Ont.

Gentlemen,-

We are pleased to advise you that the installation of the fourteen Stokers which we put in our Berlin plant last year, has given the most perfect satisfaction. We operated our Refinery at that plant for about 65 days, and saved slightly over half the total cost of the installation.

We are also placing an order with you, to equip the balance of our boilers at that plant, to be ready for our fall run.

Yours truly,
DOMINION SUGAR CO., Ltd.
General Manager

DAG/M

Simplest stokers built; no parts moving in contact with the fire; no grates; no losses through bars; no smoke.

A big paying investment for the large or small plant. Hundreds of them are effecting savings from 15 to 25% in plants like your own.

Write for catalog.

PEILER'S SERVICE—

THE simple matter of buying goods at one price and selling at another never made a successful business. The ***Element of Service*** is what adds permanence to any organization, and the success of such organization, is measured only by its ability to serve. The factor of ***SERVICE***—to the customer—always has been, and is, what has guided us in making connections with manufacturers of power plant specialties.

WE have had many years' experience solving difficult power plant questions, of all kinds and conditions, and the benefit of this experience is yours in dealing with us. If your conditions are not suitable for equipment supplied by us, we do not hesitate to advise what we think will overcome your difficulties.

ON this, and the opposite page, a few of our lines are shown. In our opinion, after long experience, with many tests and trials, they are the best, will stand up the longest, and give the most efficient service, of any that are made on the continent.

We solicit your enquiries.

How Long Does Your Cold Pipe Covering Last?

The life of any cold pipe covering in service depends almost entirely on its ability to resist moisture. If it is not moisture-proof, the water vapor in the air will work into it, become chilled, then condense and deposit moisture right in the heart of the covering. In a short time the insulation will be completely saturated. This not only renders it practically worthless as a heat insulator, but necessitates extensive repairs in a very few years.

On the other hand,

Nonpareil Cork Covering
For Cold Pipes

will last almost indefinitely, with very little attention. The clean, granulated cork of which it is composed does not take up moisture by capillary attraction. Furthermore, each granule of cork is coated with the natural water-proof gum by the manufacturing process. As an additional safeguard against the entrance of moisture, Nonpareil Cork Covering is coated inside and out with a mineral rubber finish, and the joints are sealed with water-proof cement.

Nonpareil Cork Covering has been on these lines for more than six years, with no apparent depreciation. Union Meat Company, San Antonio, Texas.

Full information regarding Nonpareil Cork Covering is given in a well-illustrated 64-page book which, together with a sample of the covering, will be sent, free of charge, on request.

1200 K.W. geared direct-current generator installed at Trenton Filtration Plant, Trenton, N.J.

The Way to Generate Direct Current

Connect a standard-speed, direct-current generator, which operating men understand and can repair upon occasion, to a De Laval Steam Turbine by means of a De Laval Double-helical Speed-reducing Gear. You thus eliminate all complications and cost of transformers and rotary converters or motor generators, and secure the maximum efficiency of conversion from steam power to electric power, viz., 98½% or over. The turbine can operate on high pressure steam, exhausting to condenser, feed water heater, heating or drying systems, etc., or it can operate upon the exhaust of other units, utilizing steam that would otherwise go to waste and increasing the power output without additional consumption of fuel or the installation of more boilers.

All De Laval units are guaranteed as to efficiency and capacity and are thoroughly tested before they leave the shop. All parts subject to wear are made on an interchangeable basis to limit gages. Moderate stresses, low peripheral speeds, ample clearances and the best materials and workmanship insure reliability.

State steam and exhaust pressures, voltages and kw. capacity required, and ask for special booklet D 61.

MARSH and AMERICAN

Steam and Power Driven Pumps and Air Compressors

Marsh and American Pumps are especially adapted for long, hard service because they are *extra heavy* in design and of *extremely rigid construction*. Every unit is built amply strong to withstand 24-hour-a-day service and to stand up under any unforeseen strain which may be placed upon it. Piston rods on the steam pumps are extra large and made of solid bronze. The water ends are equipped with heavy cast bronze removable bushings.

This superior construction not only insures continuous and satisfactory operation, but practically *eliminates expensive shut-downs*. Marsh and American Pumps are the product of over 25 years' experience in the design and construction of high grade pumping machinery. Over 135,000 in actual service throughout the world.

The AMERICAN-MARSH LINE OF CENTRIFUGAL PUMPS is composed of both single and double suction types which are designed for heads up to 125 feet. They are equipped with wide ring oiled bearings and the single suction type has overhanging casing enabling the discharge to be taken at any angle desired.

Link-Belt's Tribute to Trade Papers

By JULIUS S. HOLL,*

Extract from an interesting article appearing in "Class."

[Editor's Note:—The conclusions of the head of the promotion department of one of the most consistent trade and technical journal advertisers in the country on the subject of the value of this advertising is not "snap judgment," but is based on experience obtained through the expenditure of approximately $100,000 a year. The appropriation, be it noted, has been increased only as results have justified it, and the company is now using bigger space, more mediums and more trade paper advertising generally than ever before.]

THE trade paper is the manufacturer's best medium for exploiting his product.

It is the most inexpensive kind of advertising, because it keeps the message of the manufacturer before buyers in his field all the time for a nominal sum, and with comparatively little trouble involved in the preparation of the copy.

We get direct returns, yes—but we do not consider the "inquiry" the real index to the value of the advertising or the trade journal. It is a far bigger, better thing than that.

The big idea back of our advertising is to create confidence in our products, to make the buyer want what we have; to do constructive, educational advertising of Link-Belt products and Link-Belt service.

In our Chain advertising, for instance, our copy is designed to show the many varied uses of this product in the field of power transmission. Our aim is to make the purchaser think of Silent Chain when he connects up new machinery. The point I am trying to make is that we are endeavoring to do a constructive, educational kind of advertising, and that our policy has been successful in bringing results.

We realize that getting results from advertising is not a matter of running one or two or half a dozen ads. Constructive advertising takes time. Any man who starts advertising in a trade journal a staple product which does not possess startlingly new or sensational features, should realize that it will take time to get the desired results; but these results are worth waiting for. As John Wanamaker says, "Advertising doesn't jerk, it pulls."

It begins very gently at first, but the pull is steady. It increases day by day and year by year, until it exerts an irresistible force. This is particularly true of trade journal advertising.

Our sales forces are in absolute harmony with our advertising policy, a vital asset to any advertising department. One of our salesmen, who handles the clayworking trade, which is a big user of Link-Belt Silent chains, declared at a recent sales conference that the effect of our advertising in *Brick and Clay Record* in popularizing Link-Belt Silent Chains with the brick manufacturers has been largely responsible for our success in this field, and declared further that if trade papers in other fields were giving similar results, then the trade journal method of advertising was a great success.

Because we have more and more realized what the trade journals can do for us, the tendency has been definitely in the direction of large space. We formerly used comparatively small space, quarter and half pages, but now we seldom run anything less than a full page. Each ad. is carefully built, the foundation usually being a photograph of an installation in the field to which we are advertising, so that every picture tells a story of interest to the readers in that particular industry. It keeps us hustling to dig up these pictures, and to get photos of the right kind, but that makes the sort of publicity that gets the interest of the reader, because the ad. talks to him in his own language.

Our advertising is adapted to meet the condition of each industry. Our products also are too varied to permit of comment upon each; but the value of the trade journal is clearly illustrated again in our advertising in the coal mining industry. Seven years ago we used card space, with an occasional half-page "splurge," yet the volume of business received was satisfactory to our house.

Domestic Water Filtration Plant, City of Montreal, P.Q.

Staff Article

Pollution of water supply for domestic purposes is more or less incidental to every community in which growth and development are in progress, but to a greater degree when these elements are at one and the same time rapid in their movement and extensive in the matter of territorial scope. In our older established cities particularly, a stage is usually reached at which the public health is menaced by reason of impure water for domestic purposes.

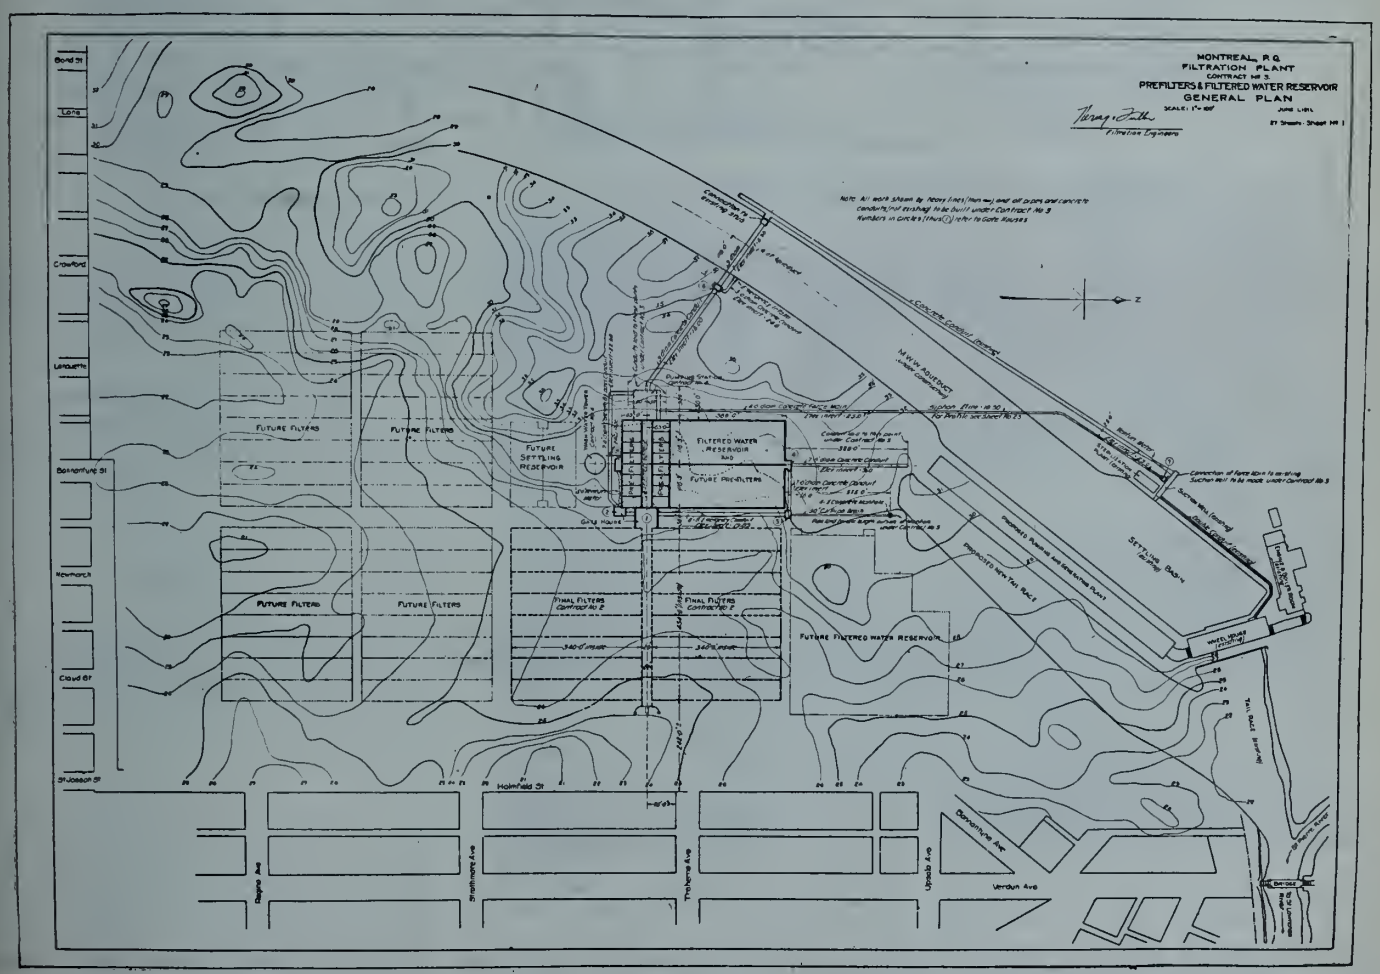
THE present water supply of the City of Montreal is obtained from the St. Lawrence River, and is distributed to consumers by two independent bodies—the Montreal Water & Power Co., a private corporation, and by a municipal waterworks plant. The former concern takes its supply from off the river shore, and since the middle of 1912 the water has been purified by means of a mechanical filtration plant. About one-fourth of the entire city population is numbered among its customers. The water supply for the municipal plant is taken from the river about five miles up stream, above the Lachine Rapids; two intakes are provided—one close to the shore and the other in mid-stream. From the entrance gate, which is common to both intakes, the water is delivered through an 8½ feet concrete conduit, to the main or low level pumping station; this plant delivering the water to the reservoirs and city mains. The average quantity of water passing through this station is approximately 55 million gallons per 24-hour day.

Initiation of the Project

Owing to the increasing pollution of the water supply in the river, caused by the growth and development of the surrounding districts and the additional population contingent to same, it was deemed advisable, if not absolutely necessary, to instal some means of purification, to aid in combating the fever epidemic that was prevalent during the fall and winter of 1909. In February, 1910, the water supply was subjected to treatment by hypochlorite of lime, this practice having been continued up to the present time. However, while the authorities were reasonably well satisfied with the results obtained from this process, steps were taken to provide a more efficient and improved water supply for the city use, and in April, 1910, Messrs. Hering & Fuller, filtration engineers, were instructed to report on the best means of securing this objective. Some few months afterwards the report was submitted and subsequently adopted, the above-mentioned engineers being engaged to co-operate with the late Major Georges Janin, then chief city engineer, in the preparation of specifications and plans for the construction of filtration works for the municipality.

General Features

The source of water supply for the operation of this system is the same as that already mentioned; that is, the intake about five miles up the river, but it is delivered to the filtration pumping station through a nine-foot concrete conduit, which taps the present supply pipe of the low level pumping station. The connection is made at the nearest point to the filtration pump house, and in addition to this supply, facilities have been provided for an emergency intake from the aqueduct, now in course of construction. This last-mentioned alternative,

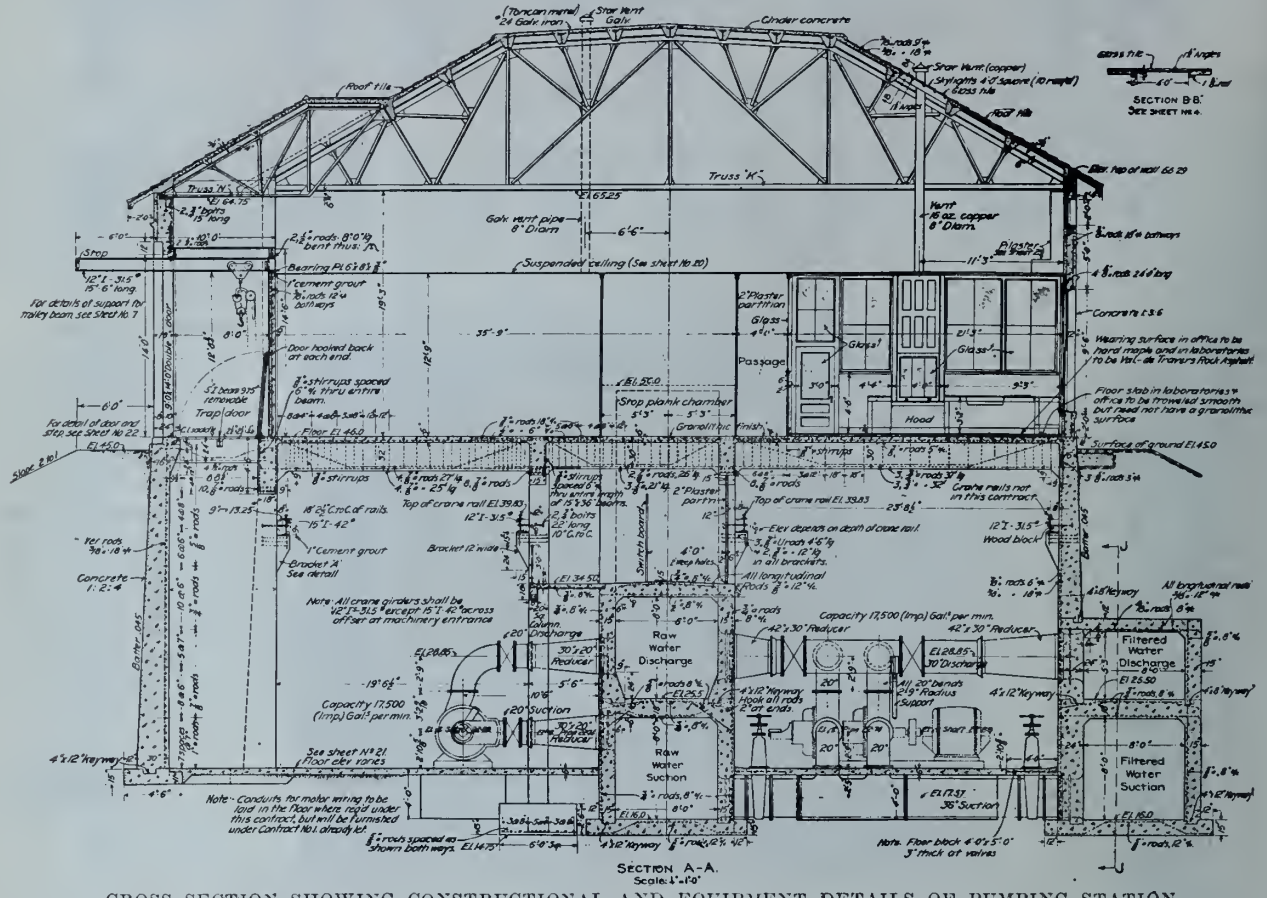


GENERAL PLAN OF FILTRATION WORKS, SHOWING PRESENT INSTALLATION AND FUTURE EXTENSION PROVISION.

however, will only be used when the main supply conduit is out of service, or additional water consumption necessitates increased capacity, as the waters of the aqueduct will naturally contain a higher percentage of impurities. The purpose of the filtration pumping station is to elevate the raw water in the supply conduit to the pre-filters, a height of approximately 18 feet, and also to furnish water at a higher pressure for washing and cleaning the pre-filters; the supply for this purpose being pumped into a large tower located outside of the main building. After passing through the pre-filters, or first and rapid stage of the purification process, the water flows by gravity through closed conduits to the final or slow sand filters, from which it passes to the filtered water reservoir, located north of and below the pre-filter beds. If deemed advisable, additional purification may be made at this point, but it is generally believed that little chemical treatment will be found necessary. Under the present system, the water from the filtered reservoir will again pass to the filtration pumping station and be pumped to the low level station, from which the high pressure pumps will force the water to the city distributing service.

With the completion of the aqueduct, now under construction, and the operation of the proposed Hydro-Electric pumping station, the filtered water will not return to the filtration pumping house, but will flow by gravity from the reservoir to the pumps in the Hydro-Electric station.

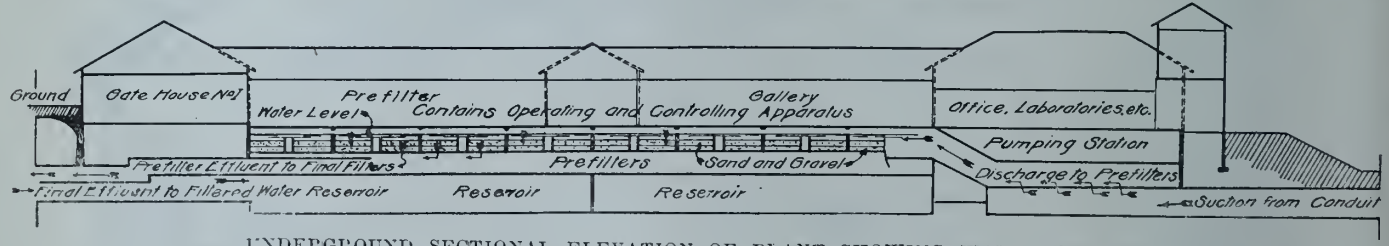
At the time the original plans were being prepared in 1910, the filtration works were designed for a nominal daily capacity of about fifty million gallons per 24-hr. day, being one-third greater than the quantity of water consumed at that time. It was, however, realized that additional filtering facilities would be required for the larger consumption of water contingent with the ever increasing population; so, with this in view, ample property was acquired in the immediate vicinity to allow for future extensions to the present plant. The remarkable growth of the city, together with the annexations of adjoining municipalities, has necessitated such large extensions to the city distributing system that the present plant will require to be operated at full capacity from the day it is put into service. The rapidly growing need of the city requirements is so apparent that steps may soon be taken to enlarge the present filtration plant to provide for a daily capacity of 100 million gallons of filtered water, or even a greater supply.



CROSS SECTION SHOWING CONSTRUCTIONAL AND EQUIPMENT DETAILS OF PUMPING STATION.

Filtration Pumping Station

The filtration pumping station, two partial views of which are here shown, is a two-storey reinforced concrete structure, 80 feet by 60 feet; one section of the pumping house being open for the entire height, with a 5-ton crane traversing the full length above the large pumping units. The top storey of the northern half of the station is reserved for the offices and general laboratories; these latter being equipped with every facility for the complete analyses of the raw and



UNDERGROUND SECTIONAL ELEVATION OF PLANT SHOWING WATER COURSE.

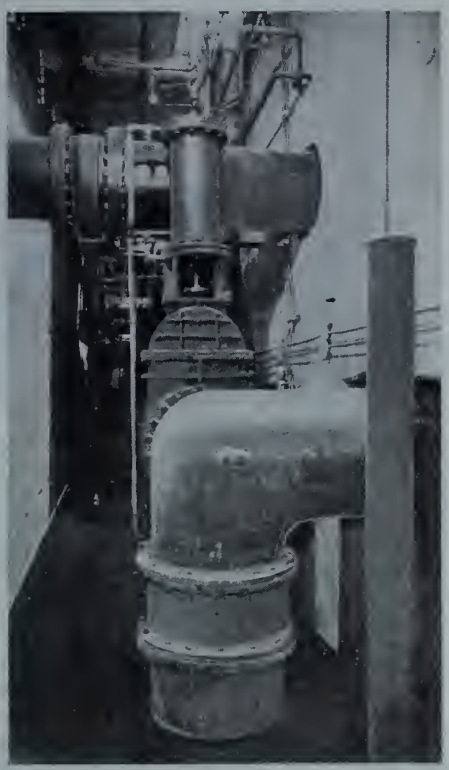
filtered water. Running along the centre of the pumping room is the raw water conduit, divided into two sections, one above the other; the lower being for the suction and the upper for the discharge. The pumping units are so arranged on either side of the lower floor that the water is taken from the lower conduit and discharged into the upper one, with a minimum of piping connections.

Main Pumping Units Layout

As shown in the plan of the pumping station, the units on the south side are connected for the pumping of raw water exclusively, while those on the opposite side of the station are connected to both the raw water conduit and the filtered water reservoir; suitable check and control valves being provided for the operation of the section desired. This method of installation will permit one or all of these units to be used for the delivery of the filtered water from the reservoir to the present low level pumping station, as this system will be necessary until the completion of the proposed hydro-electric station, when the purified water will flow by gravity to the new pumping units. In the operation of the ultimate installation, all the pumps in the present filtration plant, with the exception of the wash water and sump pumps, will be available for supplying raw water to the filters. In order to meet the capacity requirements without the alteration of standard patterns, the six largest pumps were designed with twin suction and discharge connections; all these units are controlled by hand operation. Four of them are of 17,500 gallons per minute, the other two being of 11,600 gallons capacity. The two smaller raw water pumps are of 5,800 gallons capacity, and are automatically operated by means of float switches, which in turn are controlled by the water level in the pre-filters; the pre-determined high level shutting off the power and the switch being thrown in to resume pumping operations, when the water has again fallen to a certain level. These two 5,800 gallon pumps represent about one-tenth of the total pumping capacity of the plant, and under normal conditions either one or both of these units will always be in service. The automatic control of these last-mentioned pumps, for the proper regulation of the water output, is an essential and very important feature in the operaton of the filtration plant. The significance of this can be more clearly shown by an example: For instance, suppose each filter is set to take care of three million gallons per day, or 48 million gallons for the entire plant, it would be impossible to exceed this output without the readjustment of the device controlling the rate of filtration.

Water Supply Control

Owing to the accumulation of foreign matter that will be deposited upon the upper surface of the sand beds, the filters will naturally become clogged and, therefore, will periodically require to be put out of service for a short time to permit of cleaning. When one filter is shut down for this purpose, the volume of water passing through the others is increased at the rate of three million gallons per day, and with the pumping



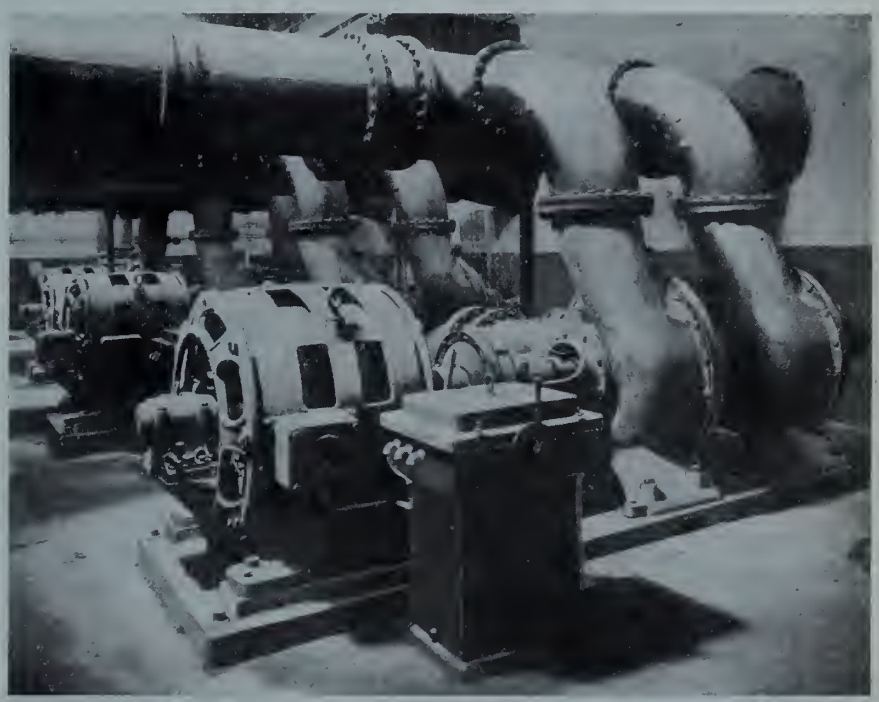
"PRATT & CADY" HYDRAULICALLY OPERATED VALVES IN PUMP GALLERIES.
Stand pipe in right foreground encloses rod from float which automatically controls their operation.

equipment delivering 48 million gallons to the remainder of the beds, the water would soon reach an undesirably high level; for this reason it is absolutely necessary that some means be provided for the control of the supply. After the pre-filter is washed, which may take from ten to fifteen minutes, it is again placed in service, the filtration proceeding at the rate of 48 million gallons per day, which in a short time will lower the level of the water to the point where the controlling float will operate the switch, and the small pump again start to operate. Another feature in connection with this method of control is that the engineer in charge is always advised as to the condition of the filters; so that when one or both of these pumps go out of service, he knows that more water is being delivered to the filters than they can use. If, after investigation, he finds the beds in good working order, he knows that the large pumps are supplying too much water, and regulates them accordingly. Should these pumps be stopped and the water continue to rise above a set level, the engineer is warned by the ringing of a loud gong, automatically started when the water reaches the danger point. This is followed by the engineer shutting down one of the large pumps.

Wash Water and Drainage Pumps

The two wash-water pumps are used to deliver water to the 120,000-gallon tank, located outside the pumping station in the wash-water tower. This supply is for the purpose of washing the pre-filters at time of cleaning; the height of the water in the tank is indicated at all times on a Winslow gauge located in the pre-filter gallery. All the pumping units, together with the blower and crane, were installed by the British Electric Plant Co. of Alloa, Scotland.

In addition to the above, two sump pumps, automatically controlled by float switches, are provided for the removal of seepage and drainage water. Their operation is such that little or no atten-



VIEW OF NORTH SIDE OF PUMPING STATION.
Showing three 17,500 gallons per minute pumps with piping arranged so as to operate on either raw or filtered water.

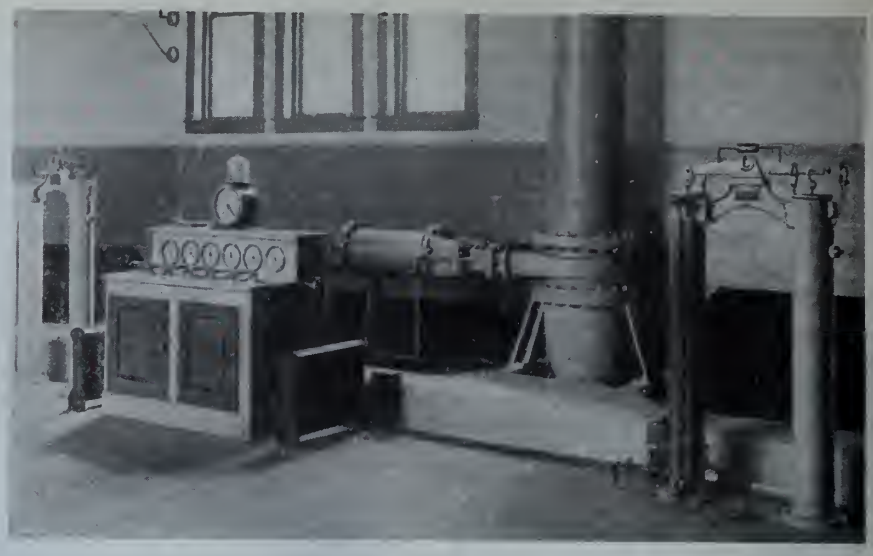
tion is required by the engineer of the station.

Pre-Filters and Control Gallery

Adjoining the east end of the pumping station, and arranged on either side of a central operating gallery are the sixteen rapid or pre-filters, each having a net filtering area of approximately 1,200 square feet. Each pre-filter is divided longitudinally by a central gutter into which empty the sixteen internal reinforced concrete wash-water gutters. The strainer and air system is made up of cast iron headers and 2-inch cast iron laterals with brass strainers spaced on 6-inch centres. The filtering material consists of 15 inches of gravel, graded into four sizes, each grade being capable of supporting the next smaller in size; the bed of gravel being finally covered with 30 inches of filter sand. Below the central operating gallery and throughout its entire length is a large double concrete conduit, the upper section carrying the raw water supply from the pumping station to the pre-filters; the effluent from the filters passing into the lower section of the conduit. These conduits are connected to the pre-filters by cast iron piping with hydraulic controlled valves.

Rate of Filtration Control

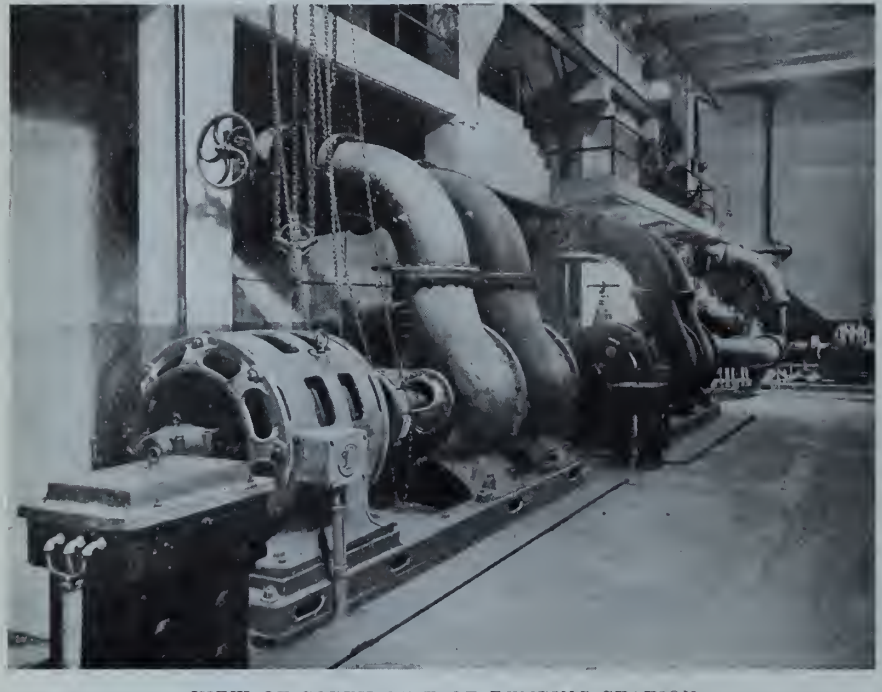
The rate of filtration in each separate pre-filter is governed by an Earl controller, each one being so connected to a master controller that the discharge from the pre-filters is automatically adjusted to that from the final filters, which in turn is again under automatic control by the volume of water that is drawn from the filtered water reservoir. The entire operation of the filtering system is practically automatic in its action, as the filtered water is delivered to the city mains at the same rate as that of consumption, without the aid of man operation of the many controlling valves. These hydraulically operated valves, both on the air and water service are of the Pratt & Cady type, fitted with cylinders of 10 inches diameter and of a length suitable to the size of the valve, the pressure required for operation being from 65 to 75 lbs. per square inch. Several of these valves are shown in the partial view of the control gallery, together with the air supply pipes and the wash water control units. The air supply is obtained from a Roots blower located in the pump room, the pressure available being about 5 lbs., this being sufficient for cleaning two beds at one time, if necessary. This air is used for agitating the sand when cleaning, a pressure of 5 lbs. being ample to overcome the head of water in the pre-filter chamber. In the cut showing the controlling unit, the various details reading from the left are: An individual controller, washing control table, Pratt & Cady hydraulically operated air valve, air supply pipe, and master controller. Two of the electric heaters, typical of those installed throughout the plant, are seen on either side of the wash water table. The various control handles, with their respective gauges, reading from the left are: —Raw water, drain, wash water, air, filtered water waste, and filtered water. The gauge showing the loss of head in feet in each bed is located in the centre by the Roberts Filter Mfg. Co., of Darby, Pa.



ONE OF THE CONTROLLING UNITS SHOWING MASTER CONTROLLER AT RIGHT.

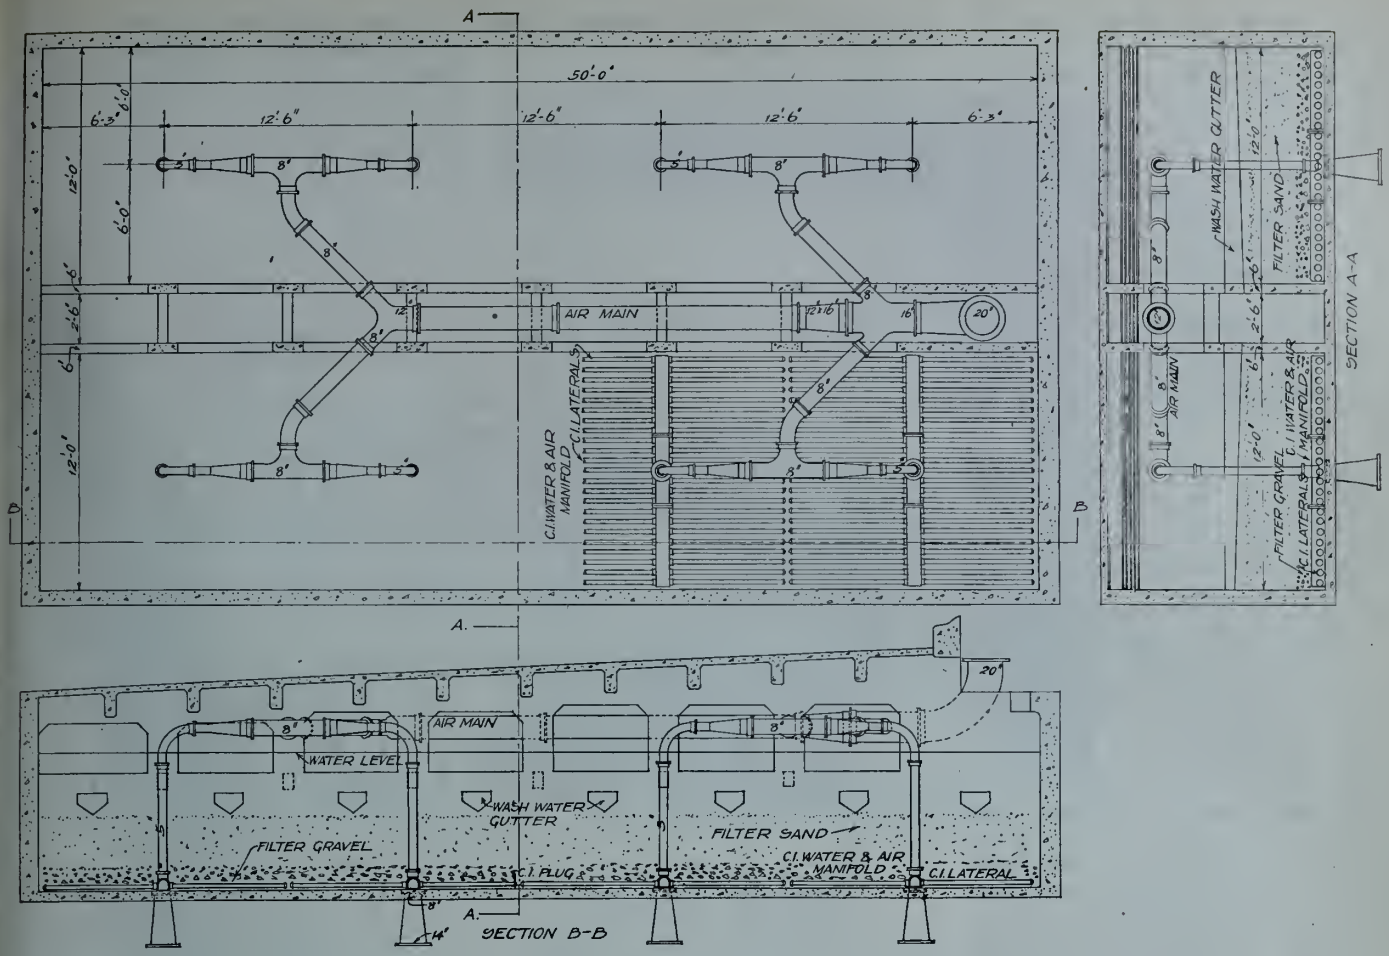
Final Filters and Washing Appliances

The final filters are somewhat similar to the pre-filters and are also arranged, eight on either side of a central operating gallery, but, owing to the slower rate of filtration, they occupy a much more extensive area than the preliminary or rapid filters. Each filter has an inside measurement of 55 by 340 feet, the length being at right angles to that of the central gallery; these filtering beds are covered with concrete-groined arches supported on piers spaced at 19 feet centres. This overhead load is carried on independent foundation blocks below each pier. The floors are flat, of five inches of concrete, and are only required to support the weight of the filtering material and the water therein. On either side of the dividing walls, light rails are provided for the operation of the Blaisdell washing machines when the filters are being cleaned. This process like that of the pre-filters, requires to be performed periodically, the machines traveling over the entire length of the filtering chamber while the upper layers of the sand are raked and washed, the dirt and other impurities that have collected since the previous cleaning being pumped away to the drains. This cleaning process can be accomplished at one passage of the machine, with only one man required

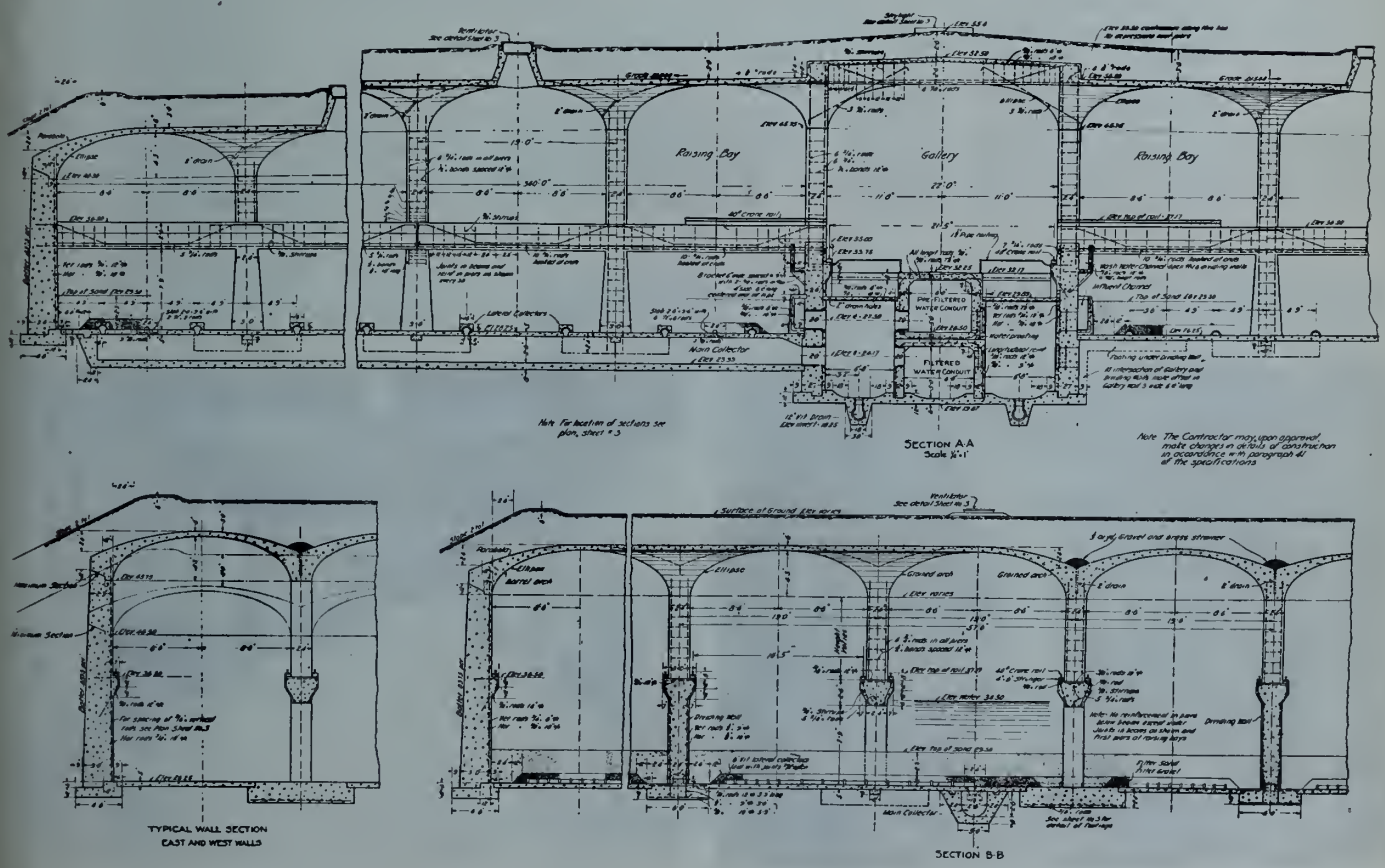


VIEW OF SOUTH SIDE OF PUMPING STATION.

From left to right: Pumping units of 17,500 and 11,600 galls. per min. respectively, and wash water pump of 1,300 galls. per min. Operating switchboard on upper gallery. Motors and pumps supplied and installed by British Electric Plant Co., Alloa, Scotland.



PLAN AND ELEVATIONS OF PRE-FILTER CONSTRUCTIONAL AND EQUIPMENT DETAILS.



VARIOUS SECTIONS ILLUSTRATIVE OF FINAL FILTERS DETAIL.

for its operation, the sand bed being left clean and uniform.

One washing machine is provided for the eight beds on either side of the central gallery and is transferred from one bed to another by means of a traveiling car that operates throughout the entire length of the department. Among the advantages of this method of cleaning are the following:—

Minimum length of time filter is out of service.

Removal of impurities from the sand is more complete than can be accomplished by any hand method, as the cleaning process can be extended to any desired depth below the surface of the sand.

Density of the sand is more uniform, as workmen are not required to walk over its surface.

Operation is more regular during the entire year, with no decrease in the effective filtering areas.

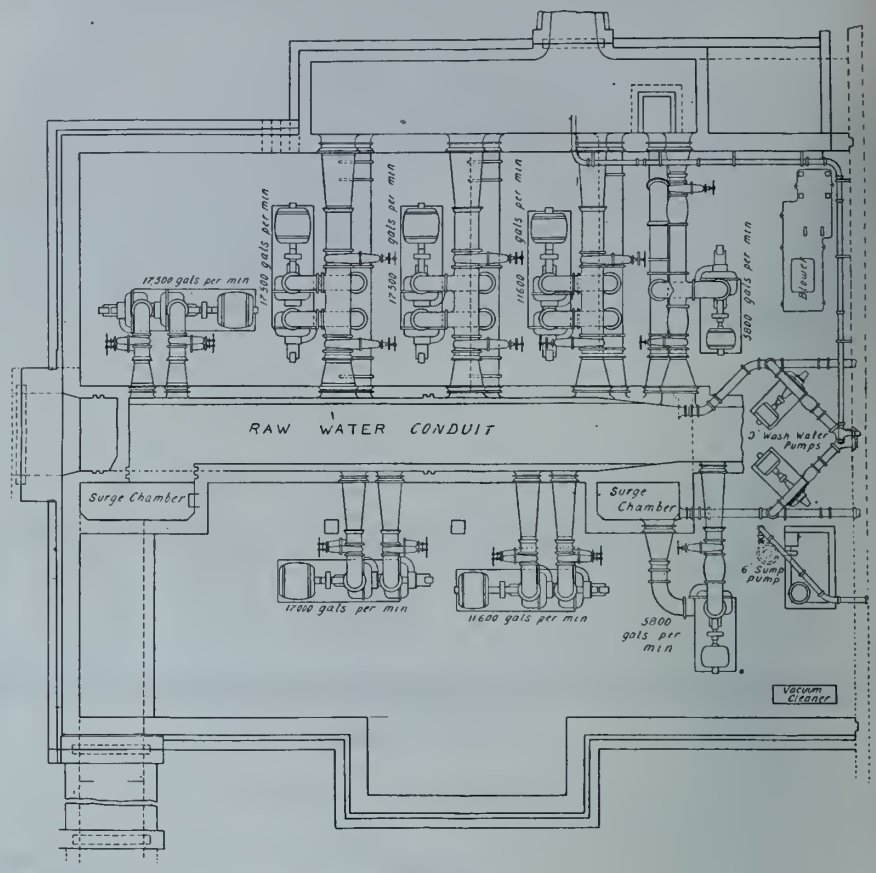
To eliminate the possibility of skin ice forming on the beds during the winter months, a heating and ventilating system has been provided; thus permitting free movement of the washing machines at all times, and in addition making the filters more healthy and comfortable for the workmen. The heating and ventilating equipment consists of a fan and numerous air ducts, these being arranged so that the heated air can be uniformly distributed over the entire area of the filters.

When the water has passed through these filters it enters into a number of half-round 8 inch tile laterals, two in each bay, and is then discharged into a central main collector, 2½ feet in diameter, extending the entire length of the filter chamber and below the floor level. From these collectors the filtered water is carried to the filtered water reservoir —a large concrete chamber about 430 by232 feet in size with an approximate capacity of 6¼ million Imperial gallons. This reservoir is located to the north of and below the pre-filters, and has a groined arch roof with the floors of inverted groined arches. There are no special features in connection with this section of the plant, except that it is employed as the chief controlling unit as already mentioned.

Electrical Operation System

The filtration plant is operated throughout by electrical power, as are also the heating and lighting. Until the completion of the city hydro-electric power and pumping station, referred to previously, the power required will be obtained from the Montreal Light, Heat & Power Co., which has a 10,000 volt transmission line near the plant. By means of branch connections, this voltage will be brought to the filtration plant transformer station where the alternating current will be reduced to 2,200 volts and then transmitted through underground conduits to the filtration buildings. This voltage of 2,200 will be used for the operation of the main pumps, but for the requirements of the smaller units and for lighting, reduction will further be made to 550 and 220 volts respectively. The entire plant will be electrically heated, two of the radiators being shown in one of the illustrations. washing machines, which use direct current, a motor-generator set has been installed to supply power to the machine motors through the three miles of double trolley lines, by which the machines are operated in the final filters.

Viewed from the exterior, the casual



PLAN OF PUMPING STATION SHOWING LAYOUT OF VARIOUS UNITS.

VIEW ALONG COMPLETED PRE-FILTER GALLERY.

VIEW LOOKING ALONG FINAL FILTER GALLERY.

observer would have little conception of the extent of this filtration plant which has a filtering capacity of over 50 million gallons per day. The few red brick buildings with their green tile roofs give but little indication of the vast amount of concrete, filtering facilities, piping and other mechanism that are essential for the successful operation of a modern filtering system. Of the ten acres occupied by the present work, over nine acres, including the final filters, pre-filters and filtered water reservoir, are entirely under ground; the location of the several sections being made known to the initiated by the position of the pumping station, pre-filter gallery building, wash water tower and the several gate houses. It might be stated here that along the roof of the final filter operating gallery are located 22 inverted oblong skylight prisms, all protected from above by means of an iron grating. While the present outward appearance gives one the impression of a few isolated buildings in the center of 100 acres of level ground with a few neatly trimmed slopes, on the completion of the progressive programme now under consideration, which comprises the construction and extension of driveways, the planting of trees and shrubs and otherwise improving the site, the apparently barren present appearance of the landscape will be found to have disappeared converting the property into a spacious park, which will not only be appreciated by the nearby residents, but will also furnish an attractive setting to one of the city's most beneficial public works. The approximate cost of the system is given in the following tabulation.

Pumping machinery, blower and cranes. British Electric Plant Co., $40,250.

Final filters and appurtenances. F. H. McGuigan, transferred to Norman M. McLeod, $673,000.

Pre-filters and filtered water reservoir. F. H. McGuigan, transferred to Norman M. McLeod, $485,000.

Pumping station, wash water tower and buildings. F. J. Jago Co., $159,500.

Interior painting. Charles Larin, $1,250.

Exterior electrical conduit system. G. M. Gest. $6,000.

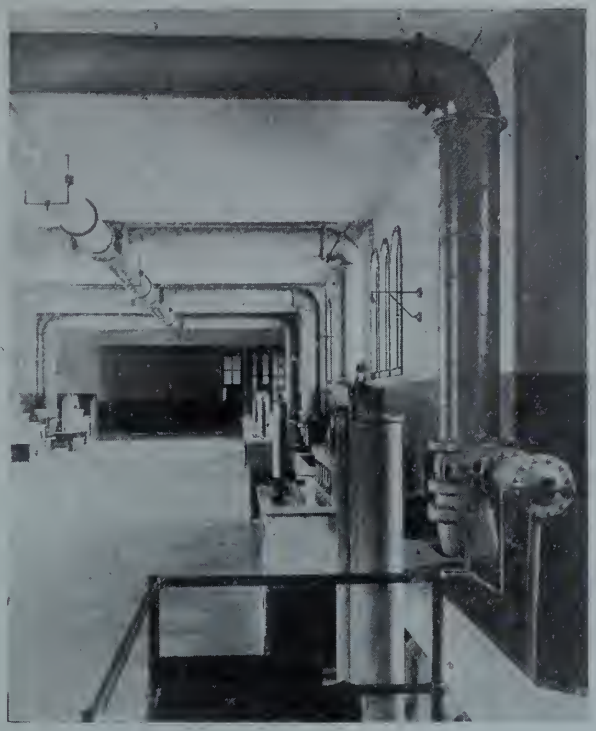
Underground electrical cables and appurtenances. Northern Electric Co., Montreal, $12,500.

Transformer building. City of Montreal, $6,000.

Approximate total value, $1,383,500.

Approximate Total Value

Owing to the great difficulty in securing suitable gravel and sand for filtering purposes, the completion of the work has been much delayed, but the final material is now being installed and it is anticipated that the entire plant will be in operation before the spring. The filtration works and other waterworks improvements are being carried out under the general supervision of Messrs. Paul E. Mercier, chief engineer of public works, and T. W. Lesage, engineer superintendent of water works, City of Montreal.



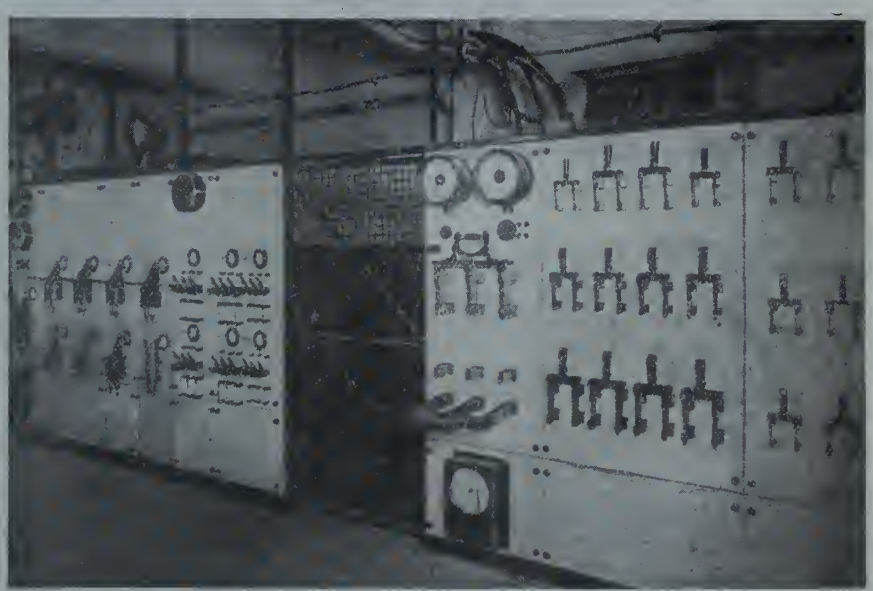
PART VIEW OF CONTROL GALLERY.

AN EIGHTEENTH CENTURY PUMPING ENGINE

IN a recent paper before the Institution of Mining Engineers, England, the authur W. T. Anderson referred to an engine which was installed at the Gregory mine, near Ashover, in 1774. The accompanying illustration of the engine is photographically reproduced from an original drawing made by Francis Thompson, and still in the possession of J. B. Gregory, of Ravensnest. The document is inscribed "Multum in Parvo by Fr. Thompson, 1774—A Draught of the fire engine at Gregory's Mine. Near Ashover." The description, with its somewhat quaint original spelling retained, is given below, for which, and the illustration, we are indebted to *The Engineer*.

Whether Thompson at this time was a representative of the manufacturers, or was the actual designer, is not clear. He may have been both, especially as it was a custom of the period to pay for machinery by result, either in the form of a percentage on the quantity of minerals raised, or on the number of strokes recorded. It has been suggested that Thompson's 1774 engine was manufactured by Boulton & Watt, but this, Mr. Anderson thinks, is more than doubtful, as Watt did not go to the Soho Works until that year, the patnership between the two eminent engineers being arranged in 1775. The machine also was of earlier design than their standard type —without a separate condenser. It seems, however, that a few year later, namely, in 1782, heavy disbursements were made by the Gregory Co., to both Thompson, and to Boulton & Watt, probably in connection with a new engine and pump shaft. A certain association between the three men may therefore be considered established. An entry in 1768, is of peculiar interest: "Mr. Brindley, engineer, demands for his trouble at Gregory, £4 4s. 0d."

A Description of the Engine for Raiseing Water by Fire; whose Cylindor is 42½ in. Diameter, and raises the water 61 yards a 12in. Boar.—Now, to



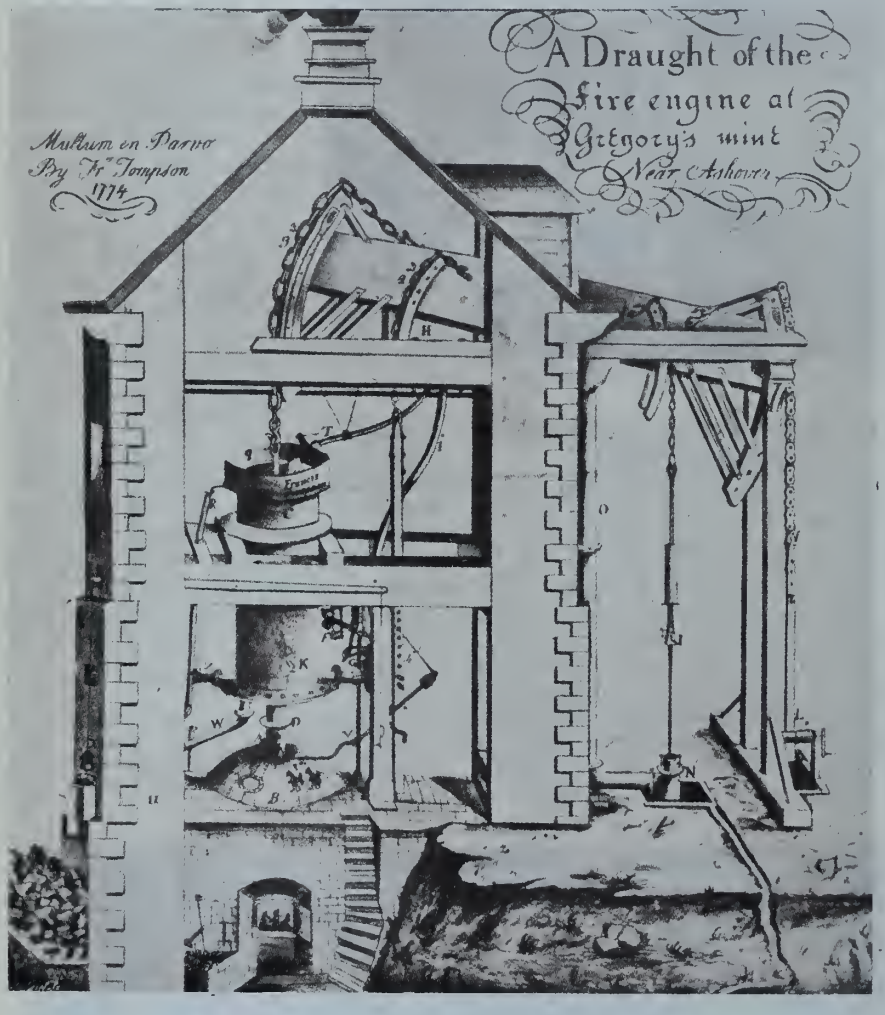
OPERATING SWITCHBOARD—POWER PANELS ON LEFT AND LIGHTING PANELS ON RIGHT.

Describe this engine, B is a large boiler whose water is Converted into Steam, C is the Cylindor, D a Pipe that Joines C the Cylindor and B the Boiler togeather, on the Lower orifice of which within the Boiler mooves a Broad Plate E by means of the regelator A, which keeps in or lets out the Steam occasionlly the Steam of the Boiler ought Always to be a little stronger then the air that when let into the Cylindor C it may be a little More than a Ballance to the Pressure of the External air that keeps down the Pistorn F, the Pistorn Being By this means at Liberty, the Pump rod will by Its Great weight of about 10 or 12 tuns will descend at the opposit End to fech a Stroak, but, as the Pistorn and Weights at the other end do not Exceed half that weight, the End of the Leaver at the Pump will always Preponderate and Descend when the Pistorn is at Liberty, then by Pulling back the Regelator, Stops all Communication of Steam with the Cylindor, then the Leaver Called the F must be Droped to turn the Injection Cock at G and that will Permit the water Brought from the Cistern H by the Pipe I to Enter the Cylindor at K which jet of Cold water being Driven all over the Cylindor Condenseth the Steam Into water again by Reason of its Coldness, and by this means its Bulk is become 14,000 times Less then it was when Steam itself makes a Vacum Suffisent for the Presure of the atmosphere.

[A Part of the Description]—To act again unballanced and to Raise the other End of the Beam with its pump to Discharge the Water at L and this whole operation of opening and Shutting the Steam Regelator and Injection Cock being performed in Little More than 3 Seconds it will Easily Produce 16 Strokes in a minuet. The Cistern H Is Supplyd with water from a Cistern Near the pit N By means of a rod fastned to an arch of the Beam which Drives the water up the Pumps O to the housewater Cistern H. In the Chamber the q at the top of the Cylindor, is a Cup to hold the water that Lies on the Pistorn, which if it Chance to Be two full will Run Down the pipe R, to the hotwell at S, and this Cup is supply'd with water from a Cistern P. In the Chamber By the Pipe T. u Is a pipe that Comes from the hot well to Supply the Boiler with water which is wasted in Generating Steam. U represents 2 Gages of Differant Lengths to Prevent the Surface of the water from Being to high Which is known thus if the Stopcock of the Shorter pipe being opened Give only Steam and that of the Longer only Water all is right. But if both cocks give Steam then the Surface of the water is to Low, or if Both gives water it is to high, hence the Cock which feeds the Boiler may Be opened to Such a Degree as always to keep the Surface of the water to its Proper hight.

W is the Eduction pipe to Carry of the water injected into the Cylindor to Condence the Steam: it is Carried to To the hot well which in the well had a Valve to Prevent the air presing up into the pipe which might hinder the Discharge of the water. X is the puffet Clack or a Valve to try the strength of the Steam which if it Be two Strong or Emoderatly Stronger then the air may Burst the Boiler; the method of trying this Strength is to Lay a weight on the Valve, and If the Steam Shall raise up more then 15 pound weight to one Inch square which is the weight of air nearly on every Square Inch it is a proof that the Steam is Stronger then the air and tho it is of a variable Strength It is never on 1 1-10 Stronger or weaker than Common air, it haveing been found By Expearience that an Engine will work well with 1 pound weight on every square Inch of the Valve X a proof that the Steam is 1-15 part Stronger then Common air. The Small pipe Z is the Snifting pipe and serves to Let out the air Injected with the water which Precipitated Air is forced into the pipe as the Steam rushes into the Cylinder being a Little Stronger then the air; Thus you see a Chain fixed to an arch of the Beam figer the 2nd, at a proper Distance from the arch 3rd. to which Chain is hung a working Plug 4 ft.. which plug has a Long slit in it and Several pinholes and pins for the Morvement of the Gears which we Call the F and Y By which the said Cocks are opened and shut as the Service requires it is Called the working plug or plug-frame which Being Set a Going according to art This Engine is most harmless and manageable of all others.

Editors Note.—As regards the foregoing description. fault cannot at least be found with the lack of detail, the quaint spelling, etc. notwithstanding.



AN EIGHTEENTH CENTURY PUMPING ENGINE.

The Gentleman in Pew 13.—At the recent annual dinner of the Hotel Association, held in the Waldorf Astoria Hotel, New York City, in addressing the meeting under the heading. "Hotels I Have Known," De Wolf Hopper, who with Mayor Mitchel was among the prominent guests present, related an amusing experience in a small town in Maine. There was a convention in the town, he said, and as the hotel was full, his company of forty had nowhere to stay. Finally, the proprietor prevailed on the clergman to open the church to provide sleeping room for the actors. During the early morning the church bell rang and the whole town was aroused.

The landlord sent the porter to see what was the matter, and the porter, a negro said, "Boss, the gent'man in Pew 13 wants two gin rickies."

High Pressure Steam Stop Valve Design and Construction

By D. McNicoll

In what follows, investigation is made of various designs of steam stop valves, particular attention being given those accessory details which contribute to the general efficiency and operation safety of each individual unit, whether for service ashore or on board ship.

IN designing high-pressure steam stop valves, the essentials to be observed are tightness, reliability, simplicity, and safety. In small sizes not exceeding 4 in. or thereabouts and of single-beat type, these essentials are obtained without much call for special consideration, but as the sizes increase the design demands careful attention. In the succeeding columns an investigation of the various designs is contributed, and prominence given to details which affect what might be termed the general efficiency and safety of the fitting.

Fig. 1 shows a type of single-beat unbalanced stop valve frequently used as a boiler stop. The same design in more or less modified form is used throughout most main steam-pipe systems, being met with as an intermediate shut-off or bulkhead stop valve. The valve shown is of 8 in. diameter, the material of chest being cast-iron, internal parts gunmetal, and the working pressure 200 lbs. per square inch. In many instances chests of this size and for this pressure are made in cast steel, but provided the design is carefully observed the choice of material is optional. For larger sizes or higher pressures cast steel is desirable. Independent of pressure, wherever superheat is present, cast steel is essential, and the internal fittings in this instance should be of a high-tension bronze, perferably a nickel alloy.

The features in the design which call for special attention are stresses in the chest due to pressure; stresses due to hardening down; stresses due to expansion of spindle with valve shut; tendency of valve to rotate when steam is flowing through; liability to fracture of seat studs. In settling the thickness of body metal, the general method is to ensure that the aggregate section is such as to allow of a safe stress per square inch of section, but on investigation it is readily admitted that all parts are not equally stressed.

In Fig. 1, assuming that the pressure is present throughout the chest and acting at right angles to the plane of section shown, the stress on the part lettered A is much higher than on the other portions. By way of illustration:—The pressure on the upper half of the outlet and half the cover is approximately 8,950 lbs.; which stresses the section on the top left-hand side to 1,061 lbs., per square inch, whereas the average stress for the aggregate section is only 891 lbs. The cover, of course, takes a portion of the stress due to frictional resistance, and the tighter the cover nuts are screwed up, the greater the assistance given to the weaker section. In a sense this is "robbing Peter to pay Paul," as it simply puts up the stress on the studs.

The stresses resulting from excessive hardening down are in many instances exceptionally high, as is often proved by the burst condition of valve lids. This hardening down is due to an attempt to overcome leakage. It appears providential that the valve lid gives way in nearly every case, or otherwise there might be far more fatal accidents in this connection. Steel crossheads and turned pillars should always be fitted in preference to cast bridges, the latter being anything but safe, particularly in the larger sizes. There is no doubt that in valves over 4 in. diameter a great benefit accrues from the adoption of a flexible seating in conjunction with the solid face. This was introduced by R. R. Bevis, J. H. Gibson and Cockburns, Ltd. With this arrangement leakage from distortion is obviated, and, in addition, there are two faces, so that if one is leaking from any cause of distortion there is always the other one to fall back upon.

FIG. 1.

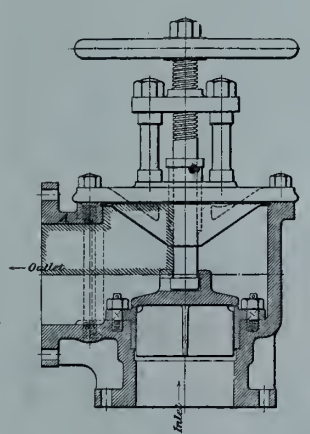


FIG. 2.

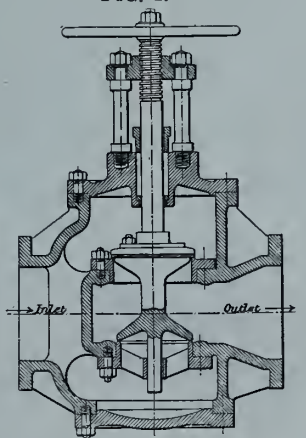

FIG. 3.

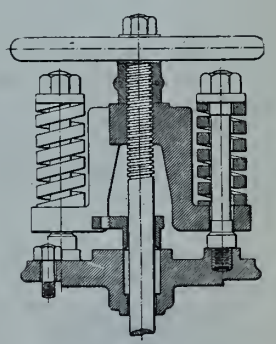

FIG. 4.

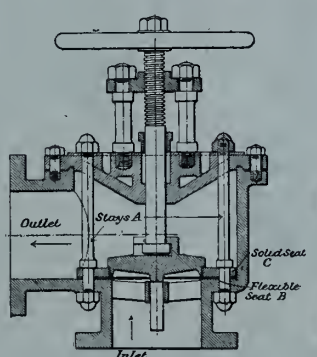

FIG. 5.

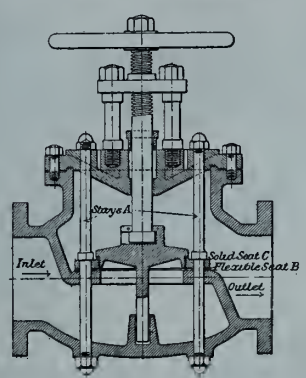

FIG. 6.

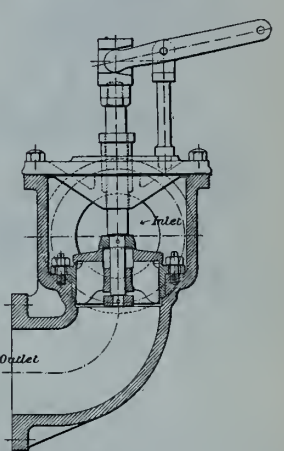

Shutting Down Hard When Cold

Another source of high stress is when the valve has been shut down hard when cold, and afterwards steam from other boilers admitted to the top of the body. Even with steam in the inlet side only a fair degree of heat is transmitted to the spindle. In each case the subsequent tendency to expansion puts a stress on all the parts. An actual experience of the author is illustrated in Fig. 2. This was a double-beat type of valve and the bottom seat was attached as shown. The valve was hardened down for a steam test, with the result that after the test a number of the manganese bronze studs from the bottom seat were found lying broken in the bottom of the chest, and all showed signs of fracture, the expansion of the spindle having caused this.

Apart from this, the design of seat is not to be recommended even if the studs do not give way, as the tendency thereby is to cause a leaky joint between chest and seat. Seats should be arranged where valves have to be hardened down so that this hardening tends to make the joint tighter, that is to say the gunmetal seat should be upon the top of the steel seat, and not below it as shown. One method of counteracting the damage from expansion is by fitting a spring crosshead. This is shown in Fig. 3, and is loaded generally from 1¼

*From a paper read before the Institute of Marine Engineers.

to 1½ times the boiler pressure per square inch of valve area, and a higher load than this cannot be put upon the valve spindle, no matter what purchase is used. In Fig. 1 stays are sometimes fitted as shown dotted. These only serve to stiffen the cover and, as will be noticed, still further reduce the section of metal at an already weak section.

The rotation of winged valves when steam is flowing is due either to a slight angle on the wings or to eddies in the steam. The valve can be prevented from rotating but to do this a pin must be fitted or other means adopted. The damage done to valves from this rotation is hardly credible, and calls for the adoption generally of pintle or centre-guided valves.

Valve Seat Fixing

The source of much trouble is the fracture of seat-securing pins or studs. In the large sizes it is quite inadmissible to drive the seats in and secure them by means of a pin or pins through the side of the chest and it is absolutely prohibited in all sizes when superheated steam is present, experience showing in this case that seats driven and secured by side pins become quite slack and allow leakage to occur. The seats in larger sizes are therefore secured in the manner shown in Fig. 1. The only way to avoid serious trouble with this design is to run a wire through the heads of all pins or through split pin holes, if studs are fitted. This prevents the fractured portions being carried to some part where serious damage may be caused.

The question of draining generally cannot receive too much attention, and means should always be provided for efficiently getting rid of all water in both inlet and outlet before a valve is opened.

In Fig. 4 a type of valve is shown which it is suggested is an improvement on that shown in Fig. 1. The first feature that attention is desired to be drawn to is the method employed so that the cover may take up a share of the bursting pressure which acts at right angles to the axis of the spindle. This consists of a tapered spigot on the chest with a corresponding tapered recess in the cover, making a metal to metal joint. The stresses from hardening down and expansion are mainly taken up by the four stays A, which also serve to secure the seatings. With this arrangement no loose parts are situated inside the chest, with the consequent prevention of damage from this source. The valve is centrally guided thus preventing rotation. A flexible seating is shown at B and when this and the corresponding valve face engage, the solid seat C and its corresponding valve face are 1-100 in. open, so that when this latter seat and face engage the flexible seating is deflected 1-100 in. Fig. 5 shows the same design of valve as in Fig. 4, but of straight through or globe type; the design calls for the same attention as in the previous case.

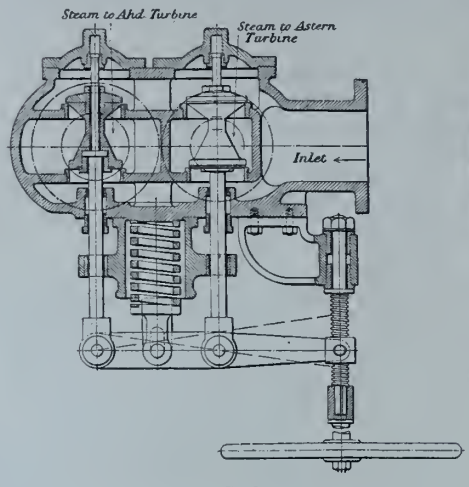

FIG. 8.

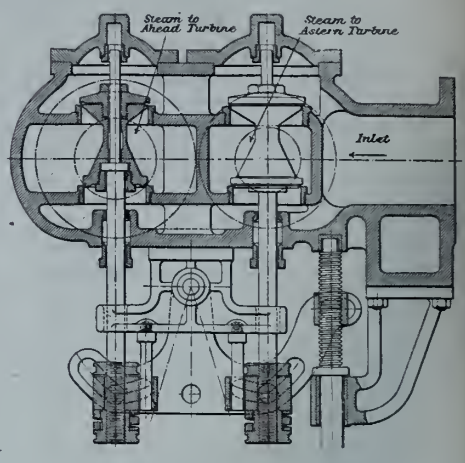

FIG. 9.

fitted or handwheel spanners used to give the same effect or gearing introduced. The difficulty is due to frictional resistance in the screw and not to the direct load which, but for that resistance, would allow for quite a reasonably sized handwheel and comparatively quick-pitched thread in valves up to about 12 in. diameter. For regulating purposes large diameter handwheels or gearing are objectionable, not enabling the valve to be handled as expeditiously as is desirable. A compromise for this type of valve is effected and is shown in Fig. 6. A pilot valve is introduced and lifts first, balancing to a certain point the pressure in inlet and outlet branches. The main valve is then lifted against much less load. This fitting is extensively adopted, but occasionally trouble is experienced from the main valve pulsating or clattering, in reciprocating machinery, due to the fluctuating flow of steam—which causes damage to the internal parts.

Solid double-beat valves got over this trouble in the majority of cases and were perfectly balanced to all practical purposes, but they had one outstanding defect—they were rarely, if ever, steam-tight, which was very unsatisfactory. For reciprocating work this did not affect the steam consumption to any extent, as it was only when the machinery was at a standstill that leakage was occurring, and if a stoppage was of any length of time the boiler stop valves could be shut down. For turbine machinery, however, leaky astern valves can very seriously affect the economy. The leakage in the solid double-beat stop valve was due to differences of expansion between the double-beat valve and the seatings in the chest and could not be got over. A solution of the difficulty was ultimately found in introducing a flexible disc to one of the beats, and the names associated with this introduction were also Messrs. Bevis, Gibson, and Cockburns, Limited. This valve has been very extensively adopted in varying designs and is exclusively used for all regulating valves in His Majesty's Navy.

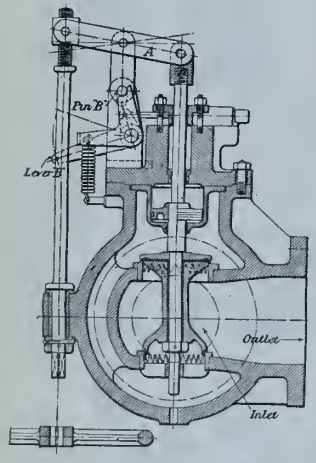

FIG. 7.

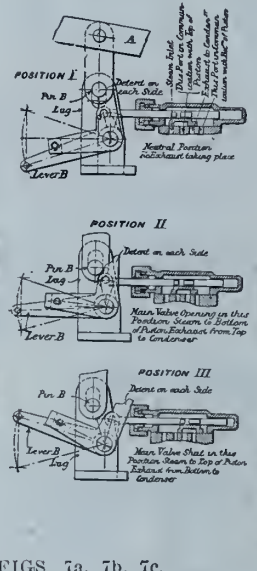

FIGS. 7a, 7b, 7c.

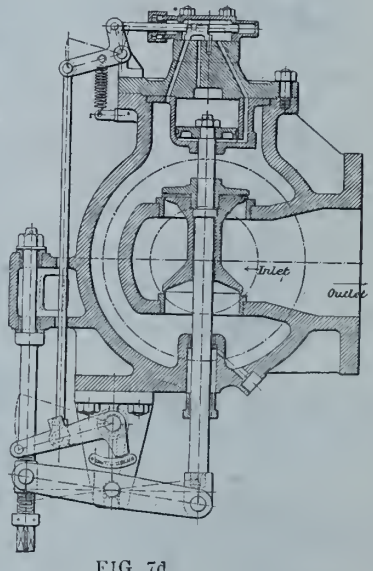

FIG. 7d.

Balanced Valves

In singlebeat valves of sizes over 4 in. and pressures in the region of 180 lb. and above, the valves are difficult to operate unless large diameter handwheels are

Double Beat Valve for Reciprocating Work

Fig. 7 shows a double-beat type of valve used for reciprocating work for regulating purposes and also as a throttle valve, doing away with the butterfly type. In this latter capacity a very light duty is thrown on any form of governing gear, while in larger sizes it obviates the necessity for employing a separate throttle engine, say of the Brown type. For ordinary opening and closing as a regulating valve the pin B is locked by the detents as shown, thus allowing the valve to be positively opened or closed. During these operations the control valve is in the neutral position, preventing steam from passing to the condenser. The operating piston has also inlet pressure on both sides of it, thus effecting a balance. The two beats of the valve have saw-formation spigots; this is to allow of close regulation, particularly where shafting is employed to bring the handwheel to a position not directly below the valve. The back-lash in this instance often allows a big jump to occur in the regulation, which is prevented with the design as shown. This jump is due to the following cause:—

With a valve of this design, that is, with steam entering outside the beats and the spindle going through the cover, there is in the first instance a closing effort due to the pressure on the increase in area of the top beat. The pressure on the area of the spindle where it passes through the stuffing-box is an opening effort. Generally the ratio of the former area to the latter is as two to one, with the result that when the valve is opened to an extent allowing half the initial pressure to be present in the outlet the efforts balance each other. A pound or two over this and an opening effort is present, with the result that the valve jumps open whatever play there is in the operating gear. With the saw formation of spigots this jump does not affect the revolutions to any extent. If instead of the spindle coming through the top of the cover it had come through the bottom of the chest the effort would have been a constant closing one, and there would be no necessity for the provision of the saw formation of spigot. Further on, valves with their spindles coming through the bottom of the chest are shown in Fig. 7d, 8, 9 and 10. The saw formation of spigots is a refinement to give close regulation from dead slow to full speed, as many doublebeat valves are made without this formation. When the valve is opened to any degree of regulation it can be shut and opened again by the throttle gear in the following manner: In Fig. 7a, b,c the throttle lever B is moved from position 7a to 7c. The control valve during this operation moves through position 7b, holding the main valve open till the detents have cleared themselves from the pin B, then with the throttle lever in position 7c the main valve closes—the levers swinging from the nut on the regulating screw. To open up again the lever B is returned to position 7a, the main valve opens up and the small tension spring returns the detent, again locking pin B and putting the valve into a position of positive control. This fitting has given general satisfaction and has been extensively adopted.

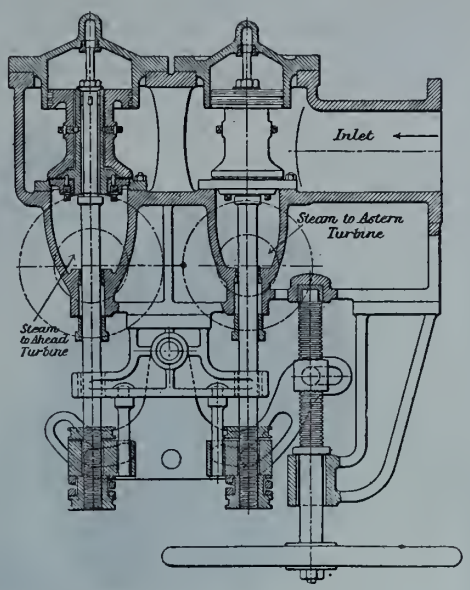

FIG. 10.

In future it is intended to make the last type of valve as modified and shown in Fig. 7d. A constant closing effort is present, which will allow of perfect regulation under all circumstances and will not necessitate the adoption of saw-formation spigots on the beats. The action under throttling conditions is similar to the former valve, with the difference that the slide valve is returned from position 7c to position 7b and 7a by the spring, assisted by the inlet pressure on the area of the slide-valve spindle where it passes through its stuffing-box.

Hardening-down stresses are alleviated by the expansion of the spindle under temperature. The illustration also shows the relative positions of ports and passages, and consequently gives a better idea of the connection between the positions of the controlling slide valve and the positions of the main valve than is shown in Fig.7.

To prevent water coming down between the spindle and stuffing-box of the main valve, as far as possible, the stuffing-box is kept high in the inside of the chest, and a drain-hole provided at the top of the packing to drain any water that may tend to accumulate there to the bottom of the chest. Provision is also made for taking away any drips that may come down.

In both the foregoing valves the design has been devised from the point of view that the relative positions of the indexes for both main and throttle valves at the starting platform are exactly similar to those where separate valves are fitted. A point of particular importance has also been carefully observed in the design, namely, that wear and tear have no effect on the efficiency of the gear.

Regulating Valve for Turbines

Fig. 8, page 58, shows a type of ahead and astern doublebeat regulating valve for turbine machinery, of which a large number have been fitted. With this arrangement one handwheel only is necessary. In a mid position both valves are shut, rotation in one or other direction opens either valve, the shut valve meanwhile becoming the medium of the fulcrum for the opening valve. In a design of this sort it is essential that the handwheel should be most clearly marked by arrows for rotation for ahead and astern. Not only should the handwheel be marked, but an index should be fitted with a pointer of considerable travel indicating quickly which valve is being operated and in what direction. This also applies to single regulating valves because, while in the majority of cases valves are shut by what is termed a clockwise motion, that is right-hand when looking on the handwheel, with the valve or extending spindle receding from the same, there are cases of extended spindles where the motion is clockwise looking in the opposite direction.

With the arrangement as shown in in Fig. 8 it is possible, if the spindle of the open valve seizes in the neck bush or gland and it is desired to shut this valve and open the other one, that instead of shutting the open valve first the other valve is opened up—a most undesirable effect. To obviate this the design as shown in Fig. 9, has been adopted, with most satisfactory results. Here the open valve must be positively shut to the point of the spigots entering the seats before the opposite valve can be opened. After this point the valve is closed and contact made with its seat by the pressure of steam on the difference of area of the two beats of the valve, plus the pressure into the area

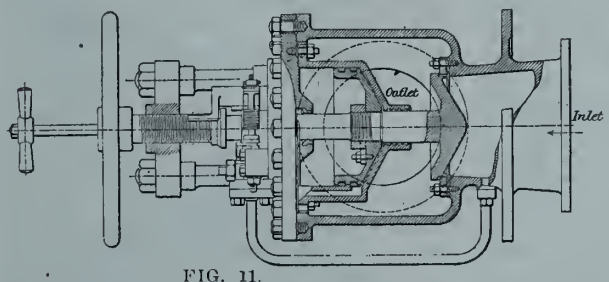

FIG. 11.

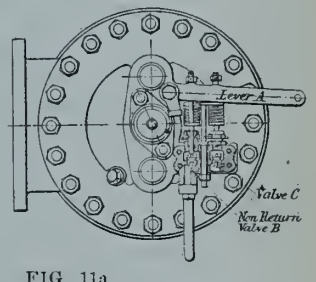

FIG. 11a.

of the valve spindle where it passes through the stuffing-box. The springs on the spindles also assist this effort. No greater closing effort can be put upon the valve. In this respect it differs from the fitting shown in Fig. 7, where, of course, the valve can be hardened on its seat to any extent.

Another arrangement of balanced valves which has a much greater final closing effort, and consequently ensures tighter valves, is shown in Fig. 10. The valves are balanced by the control valve, which forms part of the spindle, first exhausting steam from the top of the piston. Another outstanding feature is the simplicity of the chest casting, particularly desirable in cast steel. The closing effort when the valves are shut is the pressure on the area of the valves. In these designs of double manoeuvring valves and valve as shown in Fig. 7b it will be noticed there are no stresses due to expansion of spindles.

Valve for Turbine Service

A valve widely adopted in conjunction with turbine machinery for both naval and mercantile work is shown in Figs. 11 and 11a. This fitting is a combined bulkhead shut-off and emergency valve. It also fulfills the function of a self-closing valve in naval work. For ordinary opening and closing the valve is operated in the usual way by means of a handwheel. In the larger sizes it is necessary to employ a handwheel spanner. When the main valve commences to open the collar on it has an inclined plane action on the lever A which lifts the spindle of the non-return valve B, allowing steam to pass to the top of the piston and check any sudden opening tendency. The leakage past the piston rings determines the opening speed of the valve. For shutting by throttle or emergency gear, the lever A is moved further, which opens valve C; this exhausts steam from the under side of the piston, when the pressure on top of it closes the main valve. On returning the lever the main valve slowly opens up to its previous amount of lift. For naval work, where there are two or more bulkhead valves, if the pipe on the inlet side of one valve is shot away the valve is supposed to self-close with the reverse flow of steam. When this occurs the non-return valve B also closes. The efficiency of this fitting was lately demonstrated unintentionally in a fast ship of war. An exceptionally heavy sea broke over the vessel, the turbines stopped, and for some time no explanation was forthcoming; ultimately it was found that the sea had carried some gear against the deck emergency lever and moved it into the shut position, with the result that both bulkhead emergency valves were effectively shut.

Fraser S. Keith, B.Sc., for the past eighteen months editor of *Construction* has been appointed secretary of the Canadian Society of Civil Engineers, Montreal, in succession to Professor C. H. McLeod, resigned.

BLOWOFF TANKS FOR STEAM BOILERS

THE blowoff pipes of steam boilers usually discharge directly into the air, into drains, sewers, or pits; but it is not always practicable to solve the blowoff problem in this simple way. The clouds of steam that rise from the pipe may constitute a nuisance; the noise may be objectionable, or the force with which the water escapes from the pipe may be sufficient to cause prohibitive damage of some kind. In cities, for example, boiler owners are often forbidden, by ordinance, to blow their boilers off directly into the sewers, and yet there may be no place where a blowoff pipe could be discharged directly into the atmosphere without danger of scalding somebody, or without infringing upon the just rights of one's neighbors. In a case of this kind a special blowoff tank must be provided to receive the discharge, and to hold it until it can be disposed of in some approved way.

FIG. 1. AN EXPLODED BLOW-OFF TANK, PERFORATED BY CORROSION AT "A."

Blowoff Tank Explosion

The man who must use a blowoff tank usually believes that anything that will hold water is good enough for his purpose, and hence it happens that the lowly but necessary blowoff tank seldom receives the attention that it deserves. We wish to call attention, says the *Travelers' Standard*, to the importance of giving more thought to this adjunct of the boiler room, and to make our remarks more tangible and real, it will be convenient to take as a text the accident that occurred on October 27, at the pumping station of the Toledo, Ohio, waterworks, by which one man was killed in consequence of the explosion of a tank of this kind. We might equally well have taken any other accident of like nature—and it would not be hard to find another, because they occur every little while.

The exploded vessel, in this case, was made of cast iron, and it was not originally intended for use as a blowoff tank, though it is said to have been in service for this purpose for about twenty years. It was 30 inches in diameter, and before it was destroyed it was approximately 10 feet long. A part of it is illustrated in Fig. 1, and a glance at the engraving will plainly show that the metal had wasted away a good deal, from oxidation. In fact, the shell, which was originally ⅜ of an inch thick, had been reduced in this way until it was less than a quarter of an inch thick in a number of places, and at one point (shown at A in Fig. 1), the corrosion had extended entirely through the shell, so that a small opening had been formed.

The tank stood below the floor level, in a vertical position; it had, on top, two 2½-inch pipe connections for receiving the blowoffs from the boilers—its contents being eventually passed into the sewer through a six-inch pipe-connection in the side, which can be seen in the upper part of the engraving. The nozzles that appear in the photograph had been blanked off. They were, in a sense, "relics of a previous existence," for they had served no useful purpose since the vessel was first put to use as a blowoff tank.

The explosion broke the tank in two, the part shown being blown upward into the air, while the remaining portion was not moved from its original position. The photograph shows an iron reinforcing bank encircling the tank, and there were two other similar bands on the part that remained underground after the explosion. The fireman, William Grassman, stepped upon the top of the tank an instant before it gave way. He was thrown into the air, and fell to the floor directly in front of the broken blowoff connection, through which one of the boilers was being blown down. He was badly scalded by the escaping steam and water, and died from the injuries he received.

An examination made after the explosion occurred revealed an old crack extending circumferentially around the

tank for a distance of about 24 inches. It was this weakness or defect, combined with the general corrosion of the shell, which led to the explosion. When the failure occurred, the shell fractured around the entire circumstance, the line of rupture following the earlier crack.

We have no definite information concerning the conditions that made it possible for a sufficient pressure to be generated in the tank to produce this explosion, but we do know that similar accidents occur every little while. The failure here under consideration may have been caused by water-hammer action, or the discharge pipe may have become stopped up so that the tank was subjected to full boiler pressure—there being no free vent to the atmosphere. These are only surmises, however.

The Explosion and Its Lessons

Several lessons may be learned from this explosion. The first and most important one is, that every blowoff tank should be regularly examined, internally and externally, by a competent inspector. For this purpose a manhole is required (the exploded tank had none), and if the tank is set below a floor or below the ground level, sufficient space should be left on all sides to permit thorough inspections of the entire surface.

Secondly, every blowoff tank should have, as a safety feature, a vent of ample size, opening freely to the atmosphere. Under ordinary conditions the vent pipe conveys nothing but steam, but it might be of great value in relieving the pressure on the tank in case the discharge pipe should become stopped up.

The third lesson is, that blowoff tanks should be well designed and constructed. Under normal conditions a blowoff tank, if properly installed and operated, would not be subjected to a pressure exceeding (say) 25 pounds per square inch, but something occasionally happens, as in the present case, to interfere with the normal conditions, and the pressure may then be so greatly increased that the tank will give way unless it has been constructed with a contingency of this kind in mind, and provided with an ample factor of safety. Possibilities of this kind have been seriously considered by engineers, and, as a result, the laws of some States require that blowoff tanks shall be strong enough to safely withstand the full pressure carried by the boilers with which they are connected. The additional expense to which the owner may be put, in order to make a tank amply strong, is not very great, and the security that is obtained in this way is well worth what it costs.

Attention should be called to the danger of suddenly opening a blowoff valve and discharging the contents of a boiler into a blowoff tank that is already nearly full of water. Such a procedure inevitably produces a considerable pressure in the tank, particularly during the time that is required to establish a free flow of water through the outlet pipe. In fact, it is reasonable to suppose that for a short period, at least, the tank might be subjected to a pressure approaching that in the boiler which is being blown down. It should be remembered, too, that pressure applied to a structure suddenly will exert a potential bursting effect considerably greater than that produced by the same pressure when applied gradually.

Vent Pipe Essential

Every blowoff tank should have a vent pipe which should be kept constantly in free communication with the atmosphere. Valves should never be placed in vent pipes, and every possible precaution should be taken to prevent them from becoming stopped up in any way. Moreover, it is important to note that a vent pipe may give rise to a static pressure in the tank, in case the outlet by which the water normally escapes from the tank becomes stopped up. If such a stoppage occurs, the water that is blown out of the boiler can escape from the tank only through the vent pipe, and if this pipe runs up to the roof of a building of considerable height, and is filled with water, the tank will be subjected to the static pressure that is due to this column of water. For example, if the building were 80 feet high, and if the vent pipe were of the same length and full of water, the blowoff tank would be subjected to a static pressure of approximately 35 pounds. The complete stoppage of an outlet pipe from a blowoff tank would be unusual, but it might occur accidentally or through gross neglect, and we know that accidents have been caused in this way.

Mud and scale, and possibly other substances also, are likely to collect in the bottom of a blowoff tank, in quantities depending largely upon the character of the boiler feed water. It is important to remove such accumulations frequently, to prevent the destructive corrosion of the lower parts of the tank, and to avoid any chance of the plugging of the escape pipe. A manhole should always be provided to permit such cleaning, and handholes are also convenient, in addition.

Horizontal Blowoff Tank Design

We present, herewith, a sketch showing an approved design for a horizontal blowoff tank. The sizes of the vent, inlet, and discharge pipes have been purposely omitted, because they will vary according to the size of the tank, the number of boilers that discharge into it, and other similar conditions. The area of the outlet pipe should always be greater than the combined area of the blowoffs from the several boilers, so that the water may escape from the tank freely and rapidly, and without the production of an excessive back pressure, even if all the boilers are blown down simultaneously. It is highly important, also, to run the outlet pipe full size for the entire distance from the tank to the sewer. The inlet pipe should always enter the tank at a somewhat higher level than the highest part of the discharge pipe. Otherwise, water might back up into the inlet pipe, if the tank should become filled, and a water-hammer action might result upon opening a blowoff valve.

Blowoff tanks should never be made of cast iron. The best quality of boiler steel should be used, and the thickness of the shell plates and heads, and the type of riveted joint, should be such as will give a factor of safety equal to that of the boilers themselves. It is advisable, moreover, to make the shell and heads somewhat thicker than is necessary to withstand the pressure to which the tanks may be subjected, because these tanks are usually situated in damp places, and are therefore likely to be affected by corrosion. The extra thickness of metal will insure for the tanks a longer useful life. It is wise, too, to give a blowoff tank a good coating of protective paint, both internally and externally, and to renew this coating from time to time, when the boilers are out of service, so that the tank can be thoroughly dried out.

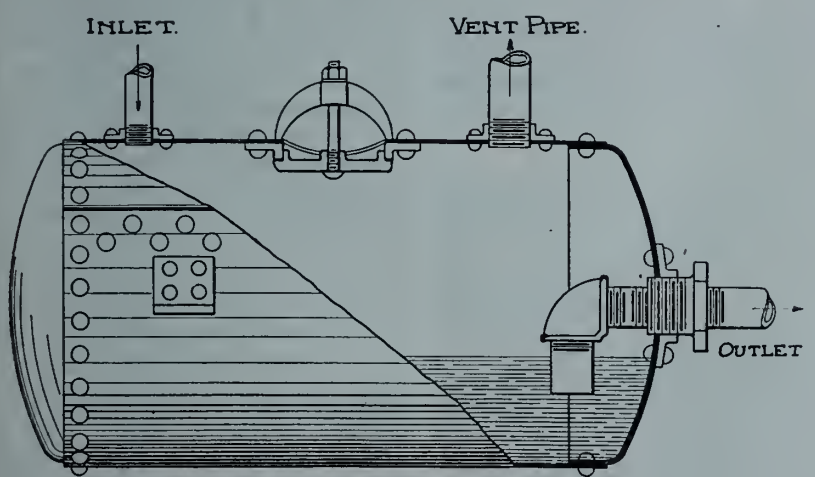

FIG. 2. APPROVED DESIGN FOR A BLOW-OFF TANK.

Richard Bell, for the last twenty-three years chief engineer of the pumping station at Sarnia, Ont., died on February 19th, aged 43.

G. Gordon Gale, formerly general manager and chief engineer, Hull Electric Co., has been appointed vice-president and general manager.

Steam and Its Generation

STEAM POWER ECONOMICS*

By C. E. Stromeyer.

THE present war, with its accompanying high prices and the possibility of a trade war after the conclusion of peace, has naturally directed attention to many economic questions, including those relating to steam boilers.

Discussions about the difference between English and German economic systems of operating factories have revealed that abroad great harmony exists between the State and manufacturers, and, as a consequence, German works have adopted systems which commend themselves because of their leading to national economy. Our customs seem to force individual works to think more of themselves than of the country's welfare. Here we need only concern ourselves with the fuel question which is briefly as follows: Our manufacturers have been spoilt by the ease with which they could obtain the very best coal in the world. When new labor-saving appliances were invented which, while increasing the output, also increased the power required to drive them, the manufacturers filled their works with them and overworked their boilers; and as this could only be done with the best of coal, slack was for long periods a drug in the market.

Wasted Coal Percentage

Constant improvements in mechanical stokers have effected a change, but no overworked boiler can burn dirty coal, no matter whether it be fed by hand or by mechanical means, and slowly but surely colliery owners found that it did not pay to bring inferior qualities of coal to the surface. As most coal seams consist of several layers, of which some are rich and others poor, the poorer layers of worked seams are often left underground and buried for ever, because to mix them with the richer ones would disproportionately lower their value.

According to recent statements by coal experts, this wasted coal amounts to 25 per cent. of the output. This national waste is due largely to our almost universal practice of overworking boilers. Bunker coal for steamers must, of course, be as free as possible from mineral matter, and export coal has also to be reasonably pure, but there is no reason, except want of boiler power in our factories, why inferior coal should not be burnt wherever it can be got. It is done on the Continent of Europe, because first-class coal cannot be obtained, but there the works provide themselves with ample boiler power, and on the whole they obtain a higher efficiency than we can hope for with our superior coal but hard-worked boilers.

Coke as Fuel

Somewhat similar remarks might be made about the burning of coke. It is a by-product of the gas works of towns, and might with gas be a valuable by-product of works which would make it their business to produce sulphate of ammonia and the volatile oils of distillation. Coke ought, therefore, to be a cheap fuel. At present, however, its production is limited, and those consumers who are compelled to use it as a fuel can be made to pay so heavy a price for it, that the profits can be used for relieving the rates. Steam users naturally do not like coke, partly on account of its relatively high price and partly because it would require larger boilers than the present ones in which to burn it with as good effect as the best coal. Thus, here again, our habit of getting the highest possible duty out of our boilers may be looked upon as being one of the causes, though perhaps only a secondary one, which hamper our coal-tar industry.

Our present practice may possibly be more profitable to the individual factories and collieries than to those of the Continent of Europe, though this is a moot point, but there can be no doubt that this practice is very wasteful of our national coal resources, and it is to be hoped that after the war encouragement will be held out to those who, without loss to themselves, will assist at national economy.

Take the simple case of a shipowner who has to decide for what speed a ship, which he contemplates ordering, should be designed. He knows that with a low speed his ship cannot command paying freights, and, going to the other extreme, he also knows that if he fills his ship with engines and boilers, there will be no room for cargo, and his coal bill will be far in excess of his earnings. He will, therefore, have to decide on a medium speed which here may be assumed to be 10 or 11 knots. With the faster ship he will be able to make 10 per cent. more voyages than with the slower one, but his annual coal bill will be increased 20 per cent. and his carrying capacity slightly decreased, on account of the extra 20 per cent. of engine, boiler, and bunker capacity. Leaning on past experiences he may be able to say to himself that his prospective earnings would be about the same, no matter whether he were to decide on the 10 or the 11-knot boat. At this point national economic considerations ought to influence him, and he ought to say to himself: The 11-knot boat will carry 10 per cent. more cargo than the 10-knot boat, but it will burn 20 per cent. more coal. My profit will be the same with either speed; therefore, in order to assist my country in saving coal, I will decide to have the slower boat.

The factory owner is faced with other, but similar, problems, and will find that he too can make selections amongst a number of alternatives of which he should choose the one which, while it does not affect his profits, will be of economic advantage to the nation. It will be my endeavor to review these several alternatives.

Fuel Cost Contributories

The cost of fuel depends, of course, on the cost of labor, and that depends on the average cost of living. This will necessarily be increased after the war on account of the heavy taxation to which we as a nation will be subjected; but it is impossible to make even the vaguest guess as to the extent to which future prices of fuel will be affected by the increase in cost of fuel which may occur. We may assume that the coal consumption for a first-class modern steam engine can be reduced nearly down to one pound of coal per indicated horse power, or nearly 4 tons per year continuous working. In most factories only about one-third of the full time is worked, whereas the interest on capital is a continuous charge, and the total cost, including wear and tear, was in one modern factory found to be $60 per indicated horse power per annum, at a time when the cost of fuel was $3 per ton. Had the factory been working night and day the cost would have been $30 per indicated horse power per annum.

This compares very unfavorably with $8.50 to $12.15 per electric horse power, which is approximately the cost of continuous power production in some parts of Sweden, Norway, and on the slopes of the Alps. These districts are rapidly realizing that they can control enormous powers, and when these have been harnessed they are sure to attract to themselves many of our industries. After the war, wages now ruling are likely to be at least maintained, and the disproportion is likely to be increased. Then

*From annual report of Manchester Steam Users Association; of which Mr. Stromeyer is Chief Engineer.

also, as the United States is not going to burden herself with additional taxes, the cost of living will not be increased there. The most threatening possibility, however, is that Prussia, true to her national traditions, not to be saddled with a national debt (her present one of 600 millions being merely an industrial one created when the State acquired all the railways), may repudiate all her internal war loans, and after a few years of severe personal hardship the taxation in Prussia, and consequently the average cost of living, and with it the price of labor and of coal, will be as low as before the war.

Record of Engine Performances

We may, therefore, expect that some time after the war, our cost of creating power for industrial purposes will be greater than in other countries, so that even without considering the question of economizing our national coal resources, it will be necessary for individual works to practise extreme economy as regards coal consumption.

In order to be able to reach a reliable starting point as to possible fuel economies, I have prepared the following list of engine performances. This is merely a repetition of the work which was done quarterly during the infancy of the Manchester Steam Users' Association, for at that time it was the custom to collect and publish information about the engine performances of our members. There seems to have been a greater willingness in those days than now to let us have the desired details, for although our membership has enormously increased since then, the present list is much smaller and less comprehensive than our earlier ones.

The majority of the recorded results are from spinning mills, and these have been classified according to the type of engines used, viz., low and high pressure compound, compound using superheated steam, and to triple expansion engines. The original returns embody the amounts of coal used for non-power purposes. In those mills where a separate boiler, usually a low-pressure one, was used for burning this coal, the return may have been fairly correct, but other returns are mere guesswork. However, by combining the most reliable of the available cases, the average fuel consumed in spinning mills for non-power purposes was found to be about 0.6-lb. per indicated horse power. In ring spinning mills the quantity is probably only 0.5-lb., partly because much of this power is converted into heat, which helps to warm the rooms.

Spinning Mill Power

The deductions which can be drawn from that part of the table which deals with the cotton spinning mills are, roughly speaking, that compound engines using steam of 100 lbs. pressure consume about 3.0 lbs. of coal per indicated horse power. For high-pressure compound engines, the net consumption is about 2.15 lbs. of coal per indicated horse power, and for triple-expansion high-pressure engines it is about 1.65 lbs. of coal per indicated horse power. The few compound engines which use superheated steam do not show up as well as might have been expected, but with one exception these engines are of an old type.

These results are neither as good as the results promised by engine builders nor as those attained during trials. This

TABLE II. DATA FROM MISCELLANEOUS INDUSTRIAL PLANTS OF 300 I.H.P. AND OVER.

is but natural and should not be allowed to influence intending purchasers, for it must be remembered that a factory engine stands idle for two-thirds of its time, and that the raising of steam and the banking up of fires costs much fuel, say, 0.3 lb. per indicated horse power. If we make this further deduction we arrive at the following average net consumptions per indicated horse powers under ordinary working conditions, which are, of course, never as favorable as trial conditions, at which the makers attend and try to minimize all losses.

Old compound engines working with about 100 lbs. pressure consume about 2.70 lbs.

High-pressure compound engines consume about 1.85 lbs.

High-pressure compound engines with superheated steam consume about 1.45 lbs.

Tripe-expansion engines consume about 1.33 lbs.

Several cases in the table show how disadvantageous it is to use engines which are either too small or too large for the power produced by them, and one case demonstrates the advantage of speeding up an engine, but this remedy has its limits. No. 16 was tested with only the main and countershafting running, and showed that only about 75 per cent. of the indicated horse power reaches the spindles.

Weaving Mill Power

The information gathered from weaving mills is very unsatisfactory, for the average returns for heating and slashing, which ought to be very much more than spinning, are only about 0.8-lb. per indicated horse power; or if we deduct 3.0 lbs. net, as found for low-pressure compound engines of spinning mills, from the gross power of similar engines in weaving sheds, the coal used for heating and slashing seems to be only 0.4 lb., which is 0.2 lb. less than for heating alone. This discrepancy may be due in part to the fact that weaving sheds are flat structures and, therefore, not cooled as much by cold winds as are the high-built cotton mills. Possibly, too, the relatively heavy coal bills for power, heating, and slashing, tend towards rigid economy in the engine and boiler departments. On account of these uncertainties the following single case of a spinning and weaving mill may prove of interest, for here the heating was done by separate boilers.

Very careful records have been kept for a full year and the results work out at 1.36 lbs. of coal per indicated horse power, for power alone, and 1.23 lbs. for heating, slashing, and washing; deducting 0.6 lb. for heating, the slashing and washing process in this mill costs 0.63 lb. These works make fancy cloths—these include thick materials, for which the spinning and weaving powers are less than the average cloths, and for which the water to be evaporated in the slashing process is a maximum.

The above works produced their own electricity by means of a turbine. In some parts of the mill each loom has its own motor, in other parts a large motor is attached to the countershafts. Here the losses will be about 8 per cent. for the motor, and 15 per cent. for the countershafts, and then there will be about 10 per cent. loss between the turbine and the switchboard. The efficiency of this part of the works will, therefore, be $90 \times 0.85 \times 0.92 = 66.5$ per cent. The small driven motors on the looms will have an efficiency of about 10 per cent., so that the efficiency will be about $90 \times 0.9 = 81$ per cent. The mean efficiency for the whole mill will, therefore, be about 74 per cent. This is practically the same efficiency as determined for mill No. 16 in the table. Electricity measured at the switchboard is practically the same as brake horse power and, therefore, an electric unit is equal to about 1.5 indicated horse power.

Flour Mill Power

The tabulated results for flour mills are too few for the obtaining of average results, but the saving effected in the case of mill No. 36 is very gratifying. The data are of importance to those whose engines are of an old type, and, therefore, likely to be inefficient, because it will give some indication as to whether advantages are likely to be gained by renewing the installations on midern lines. Of course, each case must be judged on its merits.

Now it is evident from the above table that, as a rule, only about 1 lb. or 2 lbs. of coal per indicated horse power, or, say, $5 to $15 per annum, is likely to be saved by modernizing an old power plant. If, in addition, arrangements were to be made, by providing ample boiler power, for burning a cheaper quality of coal, a very great monetary saving might be effected, but unless collieries will provide inferior fuel to individual works, this desirable policy can only be carried out by large combinations of power producers.

Production and Transmission of Power

The Newcastle Electric Supply Co. has in a way shown what can be done in this direction, and their work has also revealed the difficulties which would have to be overcome in other districts than their own before success can be obtained. Their leading idea seems to have been to provide trunk wires which would do for power what railways do for goods. They provide collieries and ironworks with outlets for any power which may be produced from their waste coal and from the waste heat of their furnaces, and they thus provide the means for the sale of this power which would otherwise be wasted. This company has in some respects been favored by local conditions, but it had also to contend with serious difficulties which are even more serious in other districts. It had the advantage of promises from all the large works on the Tyne to buy power from them, and its first power stations could, therefore, be designed to work with large units and with a minimum of cost. Subsequently the North-Eastern Railway Co. agreed to purchase all its power for local traffic.

On the other hand, the Board of Trade limit on the voltage in the trunk wires made these connecting links very expensive, and as nearly every old power station had its own voltage and its own frequency of phase, practically every amalgamation necessitated the erection of entirely new installations. An initial difficulty, which has however been nearly overcome, was that the numerous corporations had the right to exclude outsiders from supplying their little districts with power; but they have seen the advantage of adapting their voltages and frequencies of phase to those of the company, and now they buy their electric power from it for the purpose of distributing it amongst their customers.

As far as can be ascertained, the charge per unit of electricity, if used all the year round without a break, has been reduced to about $22.50 per electric horse power. For eight-hourly supply, the charge would, of course, be much heavier, possibly as heavy as the cost of individual power production by a modern steam engine.

One reason why power can be produced thus cheaply is that the company with its network of transmitting wires can deal with collieries on the following lines: Each colliery can bring, or brings to bank some very dirty coal or shale, which is absolutely unsaleable. Of this fuel about 25 per cent. can be burnt in the colliery boilers, but the remainder is thrown on waste heaps and is occasionally burnt there. Now, the company, by installing a power station with ample boiler power close to the collieries, could consume all this apparently valueless fuel and produce four times as much power as was needed by the colliery. The colliery buys its quarter share and the rest is carried away in the trunk wires.

Ironworks are utilized in the same way. The heat wasted by the gases which escape from blast and other furnaces is far in excess of the power requirements, and was largely wasted, because without a trunk system to carry away the surplus power it could not be used. Now all this waste power is bought at a cheap rate and distributed.

In other industrial districts the conditions for conveying and selling power are rather unfavorable. The numerous corporations still exclude outside producers from within their boundaries, nor will they buy from outsiders, and they have not the necessary powers for building power stations outside their own districts, and thus utilizing the waste fuel of collieries. To produce cheap power from fuel, which has had to be carted to their own works, is out of the question. They also have not the necessary powers for supplying outsiders, and are, therefore, in the most unfavorable position for acting as power brokers or, intermediary for the buying and selling of power. What makes matters worse is that nearly every corporation has its own particular voltage and phase, so that it could not, even if it would, buy and sell power from and to others.

This condition of things is not likely to change until factory owners learn

that, with a proper system, they could easily be supplied with power at a cheaper rate than that at which they can produce it.

Gas From Coal

Another means of distributing power and economizing our coal resources is to convert coal into gas, distribute it in pipes and sell the by-products, thus encouraging agriculture and the coal tar industry. In a certain sense our corporations work on these lines, and even produce a third by-product—coke. The production and sale of coke might be encouraged more than it is, because it is a smokeless fuel; but here again we find the same conflicts as in the electrical field: corporation gas is too costly for cheap heating and power production, and producers of power gas are practically prohibited from introducing their pipes into towns.

It might be possible to combine the gas and electricity systems, then gas and its by-products could be produced from waste coal, and this gas could be used in internal combustion engines, to produce electricity. Unfortunately, however, the gas engine is not as reliable as might be wished, and it is also disliked because of the irregularities of its revolutions which cause flickering of lights and troubles in spinning mills. We have, therefore, to wait, but possibly not for long, for the perfection of the internal combustion turbine. At present the steam turbine seems to combine the greatest number of advantages; not only is its running very steady, but new designs are reported to be very economical.

The fuel economy question may, therefore, be briefly summarized by saying that hardly any improvement is likely to be effected in the economic working of boilers, for, as is well known, there is only a margin of about 20 to 25 per cent. to play with. Considerable pecuniary saving might often be effected by increasing the number of boilers, so as to be able to burn a poor and relatively cheap fuel if this can be got. For instance if, when best coal costs $5, dirty coal of, say, 75 per cent. heating value were obtainable for, say, $1.50 per ton, the coal bill would be reduced to one-half, but only if the local colliery can bring this dirty coal to bank and if the boilers are large enough to burn it.

Prime Mover Development

Our chief hopes will, therefore, have to be centred on engine improvements, for here large savings might be possible, because at present about eight units are thrown away for every one doing useful work. Improvements have been and still are being effected by inventors, and research workers have little scope for their activity. Research workers have already indicated very clearly that the internal combustion engine can attain a much higher efficiency than the steam engine, but the high cost of the fuel, either oil or gas, nearly balances this advantage, and constant engine troubles and repairs are both annoying and costly. Research workers have also shown that the turbine should be much more efficient than the reciprocating engine, but it is only comparatively recently that the efficiency of the steam turbine has equalled and slightly surpassed that of its older rival, and we look to inventors, rather than researchers, to reduce the remaining losses to a minimum, for the most convenient form of extracting power from coal is still the old method of burning it under a boiler. Central power stations are not limited in their choice to the steam engine for power production, and in view of the very high theoretical efficiency of internal combustion engines they very likely hope to see the internal combustion turbine brought to perfection.

From a national economic point of view, the combination of the internal combustion engine with electric distribution of power would seem an ideal one. Our collieries would then be encouraged to mine even our dirtiest coal. This coal would produce by-products for farmers and for the coal tar industries, and supply the engines with suitable gas, and our factories would receive their power at a lower cost than they could produce it.

ALBERGER MULTI-HEAD WATER HEATER.

MULTI-HEAD WATER HEATER

A VERY complete absence of the troubles usually experienced with water heaters of conventional design is claimed for the Alberger Multi-head Water Heaters, which are designed with the object of not only insuring an adequate supply of hot water, but of performing this service at a minimum cost for repairs and cleaning.

Although the closed heater of the water tube type has long been recognized as the most efficient type with regard to rate of heat transmission, its full measure of success has not been obtained heretofore by reason of such internal troubles as scale, corrosion, split tubes, leaky joints and heads, etc. In the heater illustrated herewith, every possible effor has been made, through the selection of proper materials and consistent design, to overcome these recognized defects.

All parts coming in contact with steam or water are of cast iron or copper; the shell, tube heads, water channel, and steam and water heads being of special cast iron of non-corrosive properties, while the tubes are of pure copper, which, being homogeneous, is not subject to splitting and other defects resulting from the segregation of brass.

All water and steam connections are on the body of the shell, avoiding the necessity of breaking joints to get at the heating surfaces. Straight tubes of small diameter are employed because of their high efficiency, which is still further increased through being provided with spral corrugations. The self-cleaning action due to the rotation of the water while passing through the tubes, maintains a high degree of constant efficiency.

Considerable interest centres on the use of floating heads into which the tubes are expanded at one end of the heater, provision for proper expansion being necessary to allow full benefit to be obtained from other features of the design. The difference of expansion between the initial and final tubes through which the water passes, is taken care of by dividing the tubes into groups, each group having a separate floating head at one end, the grouping of the tubes reducing the difference of expansion to a point which eliminates tube troubles

The Alberger Heater Co., Buffalo, N. Y., build this heater in capacities varying from 200 to 200,000 gals. per hour, and in various types for hot water service in hotels, laundries, office buildings, public institutions and factories.

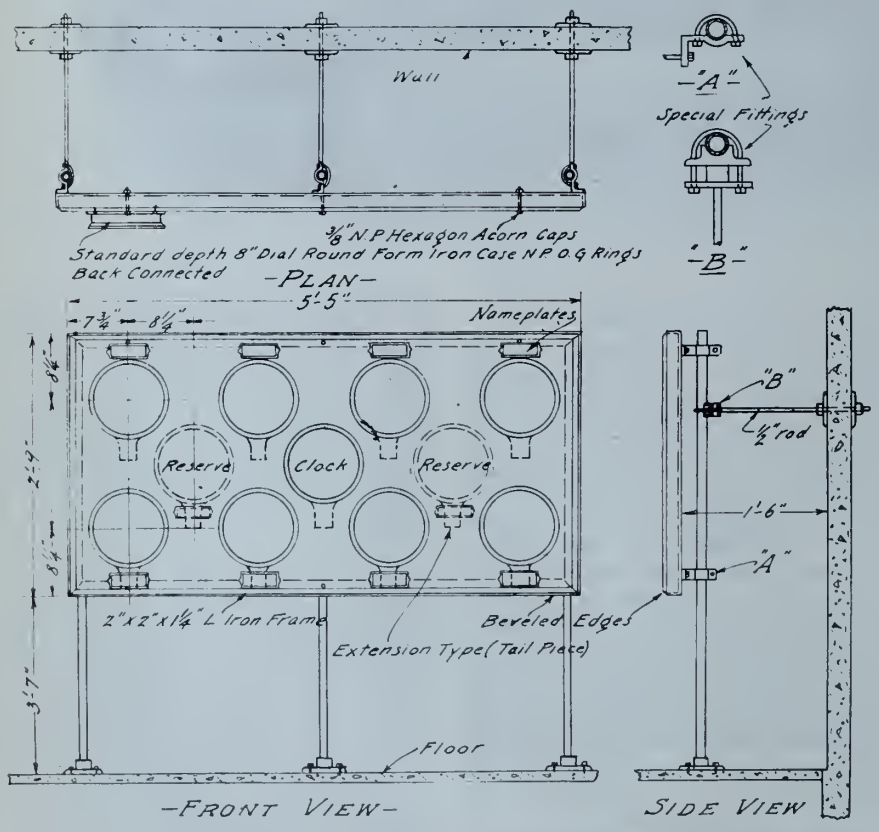
INDICATING AND RECORDING INSTRUMENTS FOR THE POWER PLANT

By T. W. R.

THE proper selection and installation of indicating and recording instruments for the power plant is a subject which is seldom given but a passing thought as compared to the operating apparatus, though nevertheless a deciding factor in the recording of operations, also in the finish and appearance of the plant. Such references in the specifications as are usually made are not in detail, and cover merely the material of the gauge board and general nature of the instruments. In selecting an instrument for a certain application, it is extremely important to choose from the many types the most suitable equipment for that particular application, taking into consideration not only the external features and the design of fittings and fixtures, but also the fundamental principles of construction and operation, which determine the accuracy and scale characteristics.

The Gauge Board

The gauge board itself should be free from flaws and seams, and have neatly bevelled edges, the standard for which is ½ inch. The bevel protects the edges from chipping. Usually a board of 2 ins. thickness is required, according to the size of same, and, in the opinion of the writer, this, together with all switchboards, should harmonize and be furnished preferably in dull black marine slate. To support the board uniformly, and proportion the stress upon same, the ends and sides should be enclosed for this thickness of board in a 2-in. x 2-in. x ¼-in. angle iron frame, thereby avoiding an undue amount of strain upon any one point. The board is bolted to the frame with finished nickel-plated hexagon acorn caps for the bolt heads showing on the face of the board, use being made of ¼-in. fillers to prevent the frames from projecting beyond the bevelled edges. The supports are shown in detail in the illustration and consist essentially of 1¼-in. iron pipe and cross braces thoroughly bolted to the frame and having ½-in. rods through the wall with flanges each side of the same. These are connected with special fittings as purchased upon the market, details of the latter being shown. The construction of the frame and supports should be neatly done. Several methods of support may be considered in accordance with the requirements of local conditions or preferences. those having no portion of the angle iron supports and braces showing below the board are desirable, though such are more costly and present a maximum of objectionable structural work as viewed from the sides. Allow a clear space of 18 inches back of the board for access to connections.



LAYOUT OF INDICATING AND RECORDING INSTRUMENTS FOR THE POWER PLANT.

Instrument Mounting

The instruments should be neatly mounted on the board, installing each with a clearance of about 2 in. between their overall outside circumferences and with a clear space along the outside edges of about 3 in. The board should be designed so that space will be available for the mounting of additional instruments, these often becoming necessary as the plant enlarges. All instruments on the board should be with back connection and have standard depth cases, uniform in size, design, material and finish, those having the name of the manufacturer, etc., in raised or large type upon the front of the same, are, in the writer's opinion, detrimental to the good appearance of the board. Dials 8 inches in diameter with round form iron cases and nickel-plated O. G. rings, are more generally used. Instruments of other than round form are indicated upon the sketch as shown dotted. While not as desirable from the standpoint of good appearance, they are claimed to be more accurate, due to the arc described by a pen pivoted from a central point in an extension below the dial. In a round form instrument the pen is pivoted from the side and all working parts are necessarily somewhat smaller. being enclosed in the round case, though by simplifying such parts their use is permitted through the taking of less space. The clock should be of size, finish, etc., which will correspond in all respects to the instruments, and should be mounted on the centre of the board. A clock of round form so located will harmonize with instruments of any form though if desired a clock with a tail piece may be obtained which will be in keeping with the instruments of the extension type as shown dotted.

Each instrument upon the board should have its respective connection indicated by letters approximately 13/32 of an inch in height (with 3/16 in. space between lines), on white opal glass nameplates 1⅝ in. x 4¼ in. in size. These are enclosed in nickel-plated brass holders. The letters are depressed on the plates and filled with black enamel rubbed in, as is usually done in connection with the ordinary brass nameplate. They may be in raised type if preferred, but such are liable to destruction by chipping off. The white opal glass presents a good appearance against a background of dull black marine slate, while the letters may be in any colors corresponding to distinguishing standard colors for the painting of the plant piping system. Where wooden boards painted black are used, letters may be painted thereon in prominent, white, distinctive, letters of a size easily read at a distance.

Connections to gauges at the board should be of brass pipe, and fittings nickel-plated where in sight, with a union cock and syphon water seal placed in a convenient position on each connection, the latter forming a pocket of sufficient capacity to fill the spring with water and maintain the temperature of the same below 140 degs. Fah. Ordinarily only the recording instruments are located upon the board, with such extra devices as Venturi recorders installed adjacent thereto flush with the board top and front. It may be advisable to locate all of these in the engineer's office, visible from the outside to others of the operating staff through windows. The usual instruments are those recording the steam pressures of the low (back pressure upon the exhaust lines), intermediate and high (boiler steam header), and the temperatures of the outside atmosphere and boiler feed water. It is very often a wise precaution to allow provision upon the board for future instruments.

Eight Day Records

All recording instruments should be designed for 8-day movement, and each equipped with a non-corrosive, non-spilling pen, automatic release pen lifter, and furnished with a bottle of special red ink and ink dropper. Instruments which have a micrometer adjustable pen arm are desirable for necessary adjustments due to water column, etc. The automatic release pen lifter keeps the chart and instruments neat and clean, free from surplus ink, and allows the free use of both hands. Closing the door with the chart in place will automatically release the arm and cause the pen to return to the chart, thus eliminating the possibility of leaving the pen out of commission. Recording instruments may be obtained in moisture, dust and fume proof cases, or with water-proof cases, where necessarily submerged in a liquid.

A year's supply of charts, say 400 for each instrument, to allow for wastage, should be kept on hand, and these should be arranged for 24-hour records with the exception of the 7-day charts for the thermometer recording the temperature of the outside atmosphere. All charts should be uniformly printed with permanent figures, graduations and inscriptions, which may be easily read at a glance, they should neither blot nor smudge, and should have accurately trimmed outer edges with a hole correctly pierced in the centre of the chart. In the selection of graduations, only those necessary for the record desired should be used, for with a lesser range a closer record and reading may be obtained. Suppressed scale graduations may be used, as, for instance, the range 100 to 150 pounds, rather than 0 to 150 pounds. The lower pressures under which the instrument could operate are eliminated from the chart, and the important and effective working range spread out to utilize the full length of the scale and thus obtain closer graduations.

Charts Range

They are especially desirable in large power plants where it is desirable to show the fluctuations in boiler pressure on an enlarged scale, and may be advantageously adopted for many other purposes. Obviously charts should be of a range sufficient to record the maximum and minimum pressures. For a neat appearing record, a chart of a specified range may be selected as desired upon which the average reading will run half way between the inner and outer circumferences of the chart. Standard or stock charts, those more generally used for ordinary conditions, should be purchased, as these are more readily obtained when a new supply is required. When impossible to obtain on standard charts, graduations as desired, use the nearest standard of greater range.

Smoked charts may be obtained which eliminate all friction between the recording arm and the surface of the chart, as the tip of the recording pen arm is only in contact with the surface of the chart momentarily at intervals of ten seconds, the pen being free and clear of charts between contacts. In this way, a white record line is made on the semi-transparent smoked chart, and, after the record is complete, this is "fixed" by dipping the chart in a fixative solution. Somewhat similar in their action are the frictionless intermittent ink recorders which produce a record line by a succession of dots. Charts may be obtained in conformance with almost any requirements and many possess such novel features as the day and night border charts which designate the night section by a black border, while in the case of the 7-day charts such portions are shaded. Reverse scale charts, that is, reading from the outer edge toward the centre, are often used where apparatus is operating under a low pressure, and it is desired to obtain close time readings, with at the same time an instrument that will withstand a high pressure if occasion should demand it.

Ordering Gauges

In ordering recording gauges, to allow for calibration of the instrument at the factory, state the purpose for which they are to be used, maximum pressure to which the gauge will ever be subjected, average working pressure to be recorded, and the minimum pressure of which it is important to have a clear record. Similarly, for recording thermometers, state the purpose for which they are to be used, distance of the bulb from the instrument, maximum temperature to which the sensitive bulb will ever be exposed, average working temperature to be recorded, and the minimum temperature of which it is important to have a clear record. Each recording thermometer should be supplied with sufficient flexible, preferably bronze armored, connecting tube with a bulb of proper dimensions (according to the fitting into which it is to be inserted, usually an elbow), having a union connection and bronze socket protected by a separate bronze socket.

Recording thermometers may be obtained in several types, as for instance, those with which any temperature changes that may take place along the connecting tube or at the instrument do not affect the accurate recording of the true bulb temperatures. It is often desirable to install in engine rooms and offices thermometers for recording the temperature out-of-doors. At certain times of the year the room in which the instrument is located may be hotter or colder than where the bulb is located. With some types the temperatures at the bulb must be higher than at any other point. Where a uniform scale is desired, a type may be used which, having a larger bulb and consequently a greater mass of metal, will not so quickly respond to changes, but which is still much more sensitive than the ordinary mercury thermometer. Its sensitiveness can be greatly increased by the use of a bulb with radiating discs. The capacity of the bulb being very large compared with the rest of the filled parts of the instrument, any variation of temperature at the parts other than the bulb have no appreciable effect on the record.

For thermometers recording at the board, the temperatures of the outside atmosphere, it is necessary to install at the nearest point an extra sensitive bulb with radiating discs. These should be located where a true reading can be obtained and enclosed in a weather-proof protecting lattice box properly secured to the outside wall of the building. The bulb is extra sensitive to changes of temperature as the lattice box permits the atmosphere to circulate freely about the bulb and the radiating discs.

Indicating Thermometers

The foregoing remarks relative to size, design, uniformity, etc., of recording instruments, are intended to apply also to instruments of the indicating types. These are usually distributed to read directly from the points to which connections are made. The face of each gauge should be distinctly marked to indicate the nature of its service. All gauges, indicating or recording, should have a globe valve in each connection close to the main, also a gauge cock close to each gauge with a pet cock be-

tween. An additional pet cock is required in the lowest point of the drop leg outside of the stop cock. Connections should be made to gauges in such a way that no water will collect in gauge pipes, and so cause a false indication on the gauge, and be so fitted that the instruments will be in operation at all times. The necessary adjustments for correct readings should be made.

A gauge located in a surrounding atmosphere of intense heat should be installed with wooden blocks placed between the instrument and the frame to which it is attached. This prevents in part, the transmission of the heat by conduction to the gauge itself. To avoid mechanical injury, etc., it is desirable to use an indicating gauge in which the entire movement is independent of its case. Those reading to indicate pressures of 50 pounds and over should be provided with double Bourdon tubes. This allows the use of a tube of heavier construction, being essentially a high pressure gauge especially adapted for service on machinery or apparatus where there is more or less extreme external vibration, or violent or rapid fluctuations in pressure. such as on a locomotive or for water service, etc.

Durability Feature

For greatest durability, a gauge should be graduated to double its working pressure. With certain types of Bourdon springs consisting of flat section tubing, gauges will be satisfactory when graduated to one and a half times the working pressure, under ordinary conditions. It is a well-known fact that no mechanical instrument will give good service if worked to its capacity continually. For this reason, if a gauge is graduated to about working pressure, the spring would very soon give out. Furthermore, nearly every user of gauges has over-pressure occasionally, and if some gauges are subjected to pressures much over the dial graduation, the spring will take a set.

Auxiliary Spring Pressure Gauge

The auxiliary spring pressure gauge has a small coil spring in tension, the functions of which are to return the free end of the gauge spring to its original position, when pressure is removed, thereby offsetting any tendency of the spring towards a permanent set and eliminating to the greatest possible extent the whipping of the free end of the gauge spring under excessive vibration.

Indicating thermometers are made with 7 in., 9 in. and 12 in. scales, 9 in. scales being generally used with graduations by one degree dependent upon the range desired. Anything above two degree graduations prohibits close reading. The thermometers should each be equipped with a nickel-plated case, moveable protecting shield, brass swivel nut, bulb and separable socket of sufficient length and a cap with retaining chain. The separable socket is a protection to the thermometer against corrosion or other injury, and permits the instrument to be readily removed when desired without shutting off pressure or emptying the vessel. Thermometers are manufactured of straight or side angle pattern, left or right, or inclined to nearly any degree to suit location.

BELT DRIVE TROUBLE

I AM having trouble with a belt drive which I would like you to advise me about. The line shaft is perfectly straight and level and the machine is also level and properly squared up with the shaft. The machine pulley is 15 in. dia. and the line shaft pulley is 6 in. dia., with 6 ft. centres. When the belt is crossed one way it runs over on the tight pulley and will not stay on loose pulley without belt shifters and when crossed the other way it runs over on loose and will not stay in tight pulley. I would appreciate an explanation so that I may cure the trouble if possible.—B.W.C.

The trouble is due to one of the following conditions being near the limit, with regard to the others:—The centres are too close, or the belt is too wide, or the difference in diameter of the pulleys is too great. The accompanying diagram shows how these points affect the behaviour of the belt as described. The arrows indicate direction of movement, A being tight side of belt, and B the slack side. Sketch (a) shows the shape of A before B is in position. It will be noted that the widest part (x) is at a point midway between where the belt leaves the pulleys. When the belt is all on, the two sides press against each other so that point (x) is moved upwards, as shown in sketch (b). The tendency of A is therefore to twist in a left-handed direction, pressing B away from the reader, the reverse action being exerted by B, but the fact that A is the tight or driving side of the belt causes B to yield more than A, so that in sketch (c), side B will run onto the tight pulley with a gradual creep to the right as complained of. If the belt be crossed on the opposite hand, the reverse action will take place, as complained of. In order to dispense with belt shifters, it would be necessary to crown the faces of the tight and loose pulleys as much as possible, run with a thinner and narrower belt, increase the distance between centres or increase size of pulley on line shaft. By trying these suggestions as far as possible in rotation you should manage to cure the trouble.

PLATE WELDS IN TENSION

A WELD in tension is always an indefinite quantity as regards resistance to rupture. If well made, its strength may approximate to that of the parts joined, but in most cases it is difficult to assign a definite value to the effective strength, as can be done in the case of riveted joints, and for this reason riveted joints are to be preferred wherever riveting is practicable. It is necessary that vessels with welded joints should have a higher factor of safety than those constructed with riveted joints, and where welding is adopted it is essential certain precautions should be followed.

In recent years, fusion welding by means of the electric arc and by the gas blow-pipe system has ben largely used in constructional and repair work, while some makers of small vessels, for use in the storage of air and gas under pressure, have used one or the other of these systems of welding for the joints securing the different parts of the vessel together. Experience has shown that fusion alone cannot be trusted to unite the parts, and that hammering is indispensable to the formation of a reliable weld. In preparing the parts to be joined, their edges should be bevelled so that a V-shaped notch is formed at their junction. This should be filled bit by bit with the fused welding metal, and the parts hammered whilst at welding heat. If this is done there is a better chance of obtaining a sound and homogeneous weld.

John H. Bunting, joint manager of Bruce Peebles & Co., Edinburgh, Scotland, has been appointed general manager of the company.

OUR PRESENT EFFORTS A FUTURE ASSET

HISTORY has been made in more ways than by feats of arms since the memorable appeal for shells was made by Sir John French when in command of the British forces in France. Not the least notable of developments incident to the then crisis has been the steady increase of munitions output by Canada, with its resulting influence on our future status in the manufacturing world, and which is yet possible of little more than approximate estimation. One fact, however, stands out in strong relief amid the meantime din of industrial effort, viz., our reserve strength in men, money and material wealth.

In pre-war days the productive capacity of the Dominion, in strictly mechanical fields, was of a very limited nature, due in part to the fiscal policy which seems to be indispensable to young industrial nations during the embryonic stages of developing their natural resources and consolidating their commercial and manufacturing enterprises. Had times such as these been foretold in all their present reality, their improbability would have been readily admitted rather than otherwise.

With reference to our munitions manufacture, it may be said that this in itself is ample evidence of the first item of reserve strength, i.e., men. The use of the word "men" is, of course, somewhat ambiguous now, in view of the successful and increasing employment of women, and when we say successful, we mean more than getting out shells or fuses on time. By successful, we mean the utilization of women help in such a manner that mutual satisfaction with the results obtained will insure a future continuance whenever and wherever opportunity offers. Among the contributing factors may be mentioned equitable remuneration, facilities enabling their arrival and departure from work to be made in a manner consistent with reasonably refined custom, and the shortest hours possible that the nature of the work permits.

The successful utilization of labor from so many previously unsuspected directions is one feature, however, which is destined to have a lasting influence on future industrial conditions, not only in Canada, but elsewhere. Abnormal effects are usually the result of abnormal causes, which, if maintained long enough, come to be regarded as normal. While many of the present abnormalities will disappear in due course—even now the adjustment process is abundantly evident—they will be replaced by others of a more stable, permanently beneficial nature, for which the present period of strenuous effort will have provided the preliminary preparation.

Another noteworthy and intensely personal factor, and perhaps more important than that of actual service, is the mechanical resourcefulness which has been displayed by the staffs of hundreds of factories from ocean to ocean. In the ordinary course of events, thousands of mechanics would never have had occasion to worry about methods and devices of production to the extent at least that these latter have had to be applied in solving satisfactorily munitions manufacturing problems. Their experience with products of their own brains and hands in competition with those of erstwhile competitors and foreign specialists has given them a confidence in their own ability and a capacity for estimating and appreciating at their true value the products of others.

It has enabled them and others to judge our engineering products from every angle, and, while the ultimate growth of the country precludes the possibility of being entirely independent of foreign machinery builders, conditions during the last two years have been such that a fuller, stronger, wider, and more distinctively Canadian metal-working industry can be confidently looked forward to.

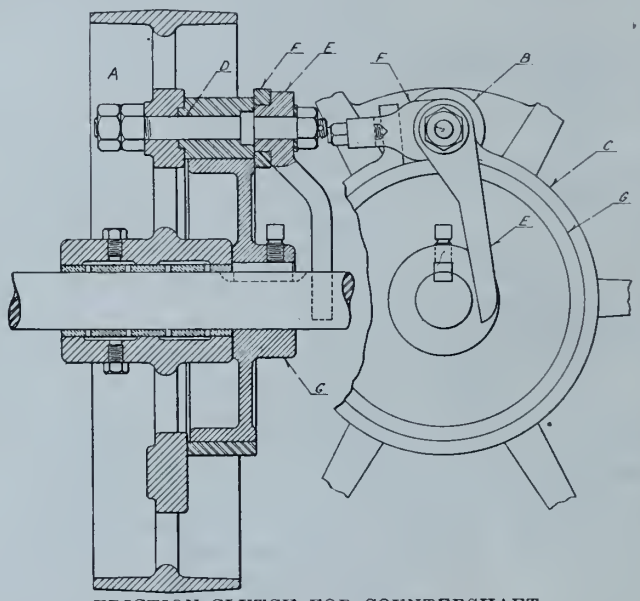
Vast though our expenditure on war has been, it must not be forgotten that our ability to meet this is due to national credit, which in turn is founded on national resources. Without the first and last of these—men and materials—our credit might long ago have ceased to exist. The recognition by the Government of the necessity for scientific research, and subsequent industrial development, will result in an ever-increasing appreciation of Canada's natural wealth. The extent of our dependence on the United States for essential materials would be brought home to us, perhaps more vividly, if the entrance of that nation into the European conflict resulted in prohibition or even restriction of much meantime exported material.

The Operators' Point of View

FRICTION CLUTCH FOR COUNTERSHAFT

by J. H. R.

THE matter of suitable drive for machine tools is an important factor not only in the production of munitions but in that of other manufactured articles as well. While recent applications of machine drives do not bear directly upon the munition problem, many of these have been developed to overcome difficulties arising out of this industry. The clutch here shown was designed and constructed by the John McDougall Caledonian Iron Works, Montreal, for the purpose of increasing the efficiency of shell turning lathes. Contrary to the general practice of an expanding spring clutch ring, the method adopted in this device has been to use a spring ring that closes on the outer diameter of the driving hub G. One end of the spring clutch ring C is secured firmly to the boss B of the loose pulley. The operating lever arm E, when forced outward by the slip sleeve (not shown), draws the two ends of the clutch ring C together, gripping the driving hub G. With the interior ring, there is generally a tendency for the clutch to creep, this being caused by the centrifugal action of the spring ring. With the type here shown, the motion, when clutch is out of action assists in preventing contact between the two friction surfaces.



FRICTION CLUTCH FOR COUNTERSHAFT.

OBTAINING DRAFT WITHOUT HIGH CHIMNEYS

By E. T. S.

ON page 28 of your issue of February is a short article entitled, "Obtaining Draught Without High Chimneys," that merits, in my opinion, more than ordinary attention, by reason that the author either has discovered something radically new in draught producing apparatus, or else he omitted to localise the case in question, in which case, the term "ordinary practice" is out of place.

Now, it is a fact that in "ordinary practice" the purpose of a chimney or stack is to "make the fire burn," in other words, to provide sufficient draught to produce complete combustion of the fuel under the boiler. Also, in the second case it carries off all obnoxious consumed or unconsumed gases. So far, I agree with our friend who now remarks, "so far so good, but this leaves in many cases much to be desired." I would like to ask what it is that is left so desirable? To continue, we read that the most efficient heating is secured by reducing fuel to carbonic acid gas. Quite true, but to produce this state in the furnace, our friend states that it is necessary "that large volumes of air must be drawn through the fire at comparatively low velocity." This statement is extremely broad, even omitting the fact that the information given is "general." We know that, for every pound of fuel consumed, a certain determinate amount of air is necessary for complete combustion. Perfect combustion is attained when the correct amount of air is admitted through the fire and also over the fire.

The next paragraph in the article says that "The best method of providing the necessary air for combustion is by means of an exhaust fan." Before proceeding further, I would like to ask, what the difference between the two draughts is to the furnace, supposing both are designed to produce the same pressure, or, whether our friend considers that a chimney draught is superior to a fan draught by reason of its origin alone. The question is absurd, because if either be designed to give a certain draft in inches, the furnace cannot detect the difference.

The subject is a live one to-day, even as to the merits of the two systems. The fan system is favored chiefly on account of the low installation cost. The chimney is high in first cost, but has a maintenance cost of practically nil; on the other hand, maintenance cost of an induced fan system is endless. In this country where we are subject to severe winter temperatures, most of us drive our boilers pretty hard in the winter. The fan is speeded up above ordinary, and, if anything happens it is liable to be serious. The chimney acts in a way, more or less automatically with you. The intensity of the draught depends on the difference between the inside and outside temperatures, and so up to a certain point the draught increases as it gets colder.

I do not pretend to understand our friend's system of stacked brushwood kept watered, unless it is intended at the air intake end of a forced draught system. Perhaps he will enlighten me?

I have written more than I intended, but it must be obvious to anyone that now-a-days a stack is not just "guessed at" for size or anything else, any more than an induced draft or forced draft system would be installed so thoughtlessly. It is the cost, the ultimate cost that counts, and these involve careful calculations and painstaking consideration.

GLOBE VALVE EXPERIENCES

By J. E. McCormack.

WITH regard to globe valve experiences the writer likes to have two globe valves on the steam supply pipe to the injector or pump, just on the same principle as one likes to have a globe between the check valve and the boiler, or a stop cock between the boiler and the throttle, because if one fails he has the other to "fall back on," as the phrase goes.

Some years ago he was in charge of one of those plants having only one globe between the injector and the boiler steam space. This globe was of the type in which the face was an internally threaded member and was screwed onto an externally threaded member which in turn fitted behind a shoulder on the valve stem. All went well for a few weeks, then one morning the face dropped from the stem and lodged in such a way as to render the injector inopera-

tive. As there was no other feed-water system installed, and only one boiler used, there was no option but to get the steam off, fix the valve, and raise steam again, thus causing a delay involving more or less financial loss to the proprietor, and which could have been avoided had there been another valve next the boiler with which to shut back the steam while the defective one was being overhauled.

Choosing a Valve

It was then decided that an additional valve should be in for meeting such an emergency should it recur, and the writer was asked what make of valve he would prefer. It was only natural that he be expected to name what was then the valve most advocated by old hands, but he was young, enthusiastic and self-willed. He wanted one which, for holding the face in place, did not depend on a nut or screw which might come loose and drop the face, or, if made too tight, would perhaps stick and refuse to budge without breaking. A valve answering to these requirements had been described in your publication. The local dealer did not stock them, but a look or two through the advertisement section disclosed the whereabouts of a sales house, and a few different sized valves and discs were ordered by letter. The only tool required when changing the discs is a wrench that will remove the bonnet; this done the old disc can be easily removed from the stem by hand and a new one slipped on. When the bonnet is returned to its place it is impossible for the disc to get out of position.

Emergency Babbitting

After a time it was found that the supply of discs for one size of these valves was nearly exhausted and to make it hold out a little longer (owing to no local dealer stocking them as aforementioned), the writer took a cue from the soft metal faces of some lubricator plugs. The old asbestos face was dug out and its place filled with melted lead. This lasted for two days, at the end of which time it had squeezed out too much. Melted babbitt metal was then tried, and as it gave very good service it was used on this size of valve for some time. An acquaintance tried the babbitt on a make of valve which used a nut to hold the face in place and effectively locked the nut by pouring in enough metal to cover the nut.

Although the writer was, and is yet, well pleased with his chosen make of valves, he has known them to be criticized by other operators, each of which had a preference of his own for some particular make, but on one occasion when talking with an engineer about valves in general, the engineer remarked, "I like those —— valves. For one thing, they are a valve you are never stuck with. The discs are easily changed, yet won't come off unexpectedly, and if you should happen to run out of discs you can remove the old face, pour in some babbitt, true it up a bit and go on again." Now, my object is not the boosting of any particular brand of valves, but what I want to impress is that this babbitt habit has helped out of difficulties at times and a few men have begun to look to it as one of their stock emergency measures. With this fact in mind we are ready for another experience, which came to the writer's knowledge just recently.

Conditions Must be Studied

The globe on an injector steam pipe was bad and no proper face for that make of valve readily procurable at the time, a few days' delay being normally unavoidable under existing circumstances, and so the operator tried the babbitt scheme for the first time. His boiler was an upright one with this globe placed close to it. Before being in use long his injector balked and investigation proved that some of the babbitt had melted and been carried down into the injector steam jet. Evidently some of the metal had also lodged in the elbow, for after a reliable face had been inserted the injector was twice put out of action by plugging with babbitt. The brand of babbitt used may have been rather easily fused, but the writer's personal theory is that since the boiler was an upright one, the steam became at times sufficiently super-heated to melt babbitt. Anyway, this latter experience proves that though some have been helped by thus using this metal it may perhaps be worse than useless wherever any degree of super-heat may even possibly exist, and "by the same token," when trying out only one valve of any make and in comparison with other valves in service it may, if placed as above-mentioned or in any other position where super-heat may get to it, appear to use softer discs than other valves when in reality it is being put to a more severe test than is the valve or valves it is being compared with, yet without the operator suspecting that such is the case.

LINE SHAFT TROUBLES

By H. Westwood.

UNDER this heading there appeared an article in a January issue of your publication. It just serves to remind me of an engineer in a neighboring works to where I was operating an electric plant. The day came when my neighbor engineer had to put a new drive belt on the engine, which was a 20 in. x 36 in. with a 14-ft. fly-wheel.

The old belt was taken off on Sunday morning and the new one put on. Monday morning arrived and found the would-be expert at the throttle. When the engine began to turn over, the belt did not run in the centre of the pulley, but far enough over to the right side to rub the wooden partition that had been placed there to prevent anyone falling into the wheel pit.

"Well, she will have to go till Sunday," was the explanation from George, "there is not enough time at night to undo the splice and re-splice it." Each day that week found the belt rubbing the partition harder until it had nearly worn it through, and as each day arrived, George had a new idea as to what might be the trouble.

Blaming the Line Shaft

One thing he was sure of, and that was the drive shaft, which was about 150 feet long, was out of line. Next Sunday arrived and with it a gang of men to line the shaft. Some understood what to do and some didn't; however, the shaft was lined and Sunday night found a tired lot of men and the shaft 4½ inches farther from the engine line on the extreme end. Monday morning came and the engine was started up, but, alas, no improvement in conditions of the belt running in the centre, and to make matters worse, several boxes burned out on the line shaft. A couple of nights that week were spent in fixing up the boxes all along the line shaft.

The following Sunday an attempt was made to jack the engine around on the bed, but did not meet with the desired success. The belt by this time had stretched considerably, and some time during Tuesday morning of the third week it took a notion to flop over and run with its back on the driven pulley. To the surprise of George, when he came to the shop he saw the belt running as nice as could be, right in the centre of the pulley, and with all haste he entered the engine room to know why and found out.

"Well, I'll just take it off next Sunday and tighten it up and it will he all right!" But George never had the chance, for the following Thursday the place was burned down.

C.A.S.E. ORGANIZE AT SUDBURY, AT a meeting of Stationary Engineers held in Sudbury, Ont., on February 28, a branch of the Canadian Association of Stationary Engineers was organized. Officers were elected and installed for the remainder of the current year at a meeting held on March 13. A Lodge Room has been secured in the Temperance Hotel Building, Station Street. W. H. Anger and J. H. Hale, executive secretary were largely instrumental in arranging the details connected with the establishment of this new branch, the former carrying out the initiation and installation ceremonies necessary for members and officers respectively. The officebearers are as follows:—Past president, A. A. Wigley, president, J. J. McCaffrey; vice-president, J. A. Peters; secy-treas., A. I. Riddell; recording secy., R. S. Wright; conductor, A. Laberge; doorkeeper, W. E. Massie. The membership of the Lodge in addition to the foregoing includes J. E. McFarlane, C. Doolittle, W. Keays, G. W. Dale, P. O. Deseron, R L. White, F. Lumley, C. Blacklock.—Brennan.

Pop of Safety Valves.—By "pop" of a safety valve is meant the instantaneous rise to almost full opening after the first tendency of the valve to move from its seat, or simmer. A satisfactory "pop" is essential to a successful safety valve. Absence of "pop" will mean a prolonged simmering of the valve which will soon score both valve and seat, especially if steam is superheated.

Question and Answer Section

Pump Suctions and Discharges.—Why is it, that in a centrifugal pump we get the suction and discharge openings of equal diameter, whereas, in the duplex type, or, in fact, any type of pump other than the centrifugal, the suction is the larger of the two? With the same lift, does equal friction exist in the suctions of either type?—Telco.

Friction losses in a centrifugal pump have a much more serious effect than in the case of a duplex or positive action pump with pistons or plungers. Centrifugal pumps attain their highest efficiency at a certain predetermined speed and if pipe sizes are reduced, the increased velocity results in considerable friction loss which reacts on the output capacity of the pump at given speeds. Hence both suction and delivery are as large as commercially practicable within reasonable limits, but always with a view to running the pump at its point of maximum efficiency. Positive types of pumps on the other hand will work at any speed from maximum to minimum, and in ordinary conditions seldom work at maximum speed continuously. Economy in discharge piping is therefore possible with positive pumps which could not be done with centrifugal pumps. The suction effect in either type of pump is identical so far as pipe friction is concerned, so that the maximum diameter permissible is adopted in nearly all cases, the pipe friction being the same for equal velocities of water.

* * *

Steam Heat Pressure.—Is there economy in carrying a high steam pressure? Will you please let me know what is the most economical pressure to carry on a boiler installed to heat a business block? Can carry from 50 to 160 lbs. per sq. inch gauge pressure. That on the radiators is, however, below atmospheric pressure.—A. C.

High steam pressures say up to 150 lbs. per sq. in., are frequently used in connection with the heating of public institutions, office buildings, etc., where floor space is valuable, as by generating at a high pressure and reducing to a few pounds pressure, the steam is delivered in a superheated condition which enables it to travel through considerable distances of piping before condensation begins to take place. Installations of this type necessitate the use of steam traps or pumps for returning the water of condensation to the boiler, whereas in small buildings and residences a gravity system is generally used, with a steam pressure of from one to five lbs., the condensed steam returning by gravity to the boiler, which is below the level of all mains and radiators.

As a result of such conditions there is more perfect combustion, better circulation, greater efficiency of heating surfaces, etc., high pressure boilers, particularly of the water tube type, are most economical if in constant use. Small installations with occasional attention, however, cannot be more suitably equipped than with low pressure boilers with pressures up to ten or twelve pounds.

* * *

Offsetting Lower Boiler Pressure.—My engine travels at the rate of 98 revolutions per minute, but my boiler is no longer rated to carry its original pressure—only 70 lbs. per sq. inch now. This gives us too much wet steam. I would like to know if increased efficiency can be secured by speeding the engine up to 105 revolutions per minute, and lagging the pulley on the main line shaft sufficiently to retain the present speed of the latter?—M. W.

A reduced rating in your boiler pressure will not prevent you from obtaining as much power from it as previously, if you do as you suggest. The steam pipes should be well covered and a separator installed next the engine, which, if run at 105 revolutions with an increased diameter of pulley on line shaft to keep shaft-speed constant, would have an increased efficiency which would offset the 10 or 15 lbs. drop in boiler pressure. Theoretically, from 98 to 105 revs. per min. equals an increase of approximately 7 per cent. As the power of an engine is directly proportional to both speed and pressure, this increase in speed equals a drop in pressure of 7 per cent., or from 75 to 70 lbs. We presume, however, that the former pressure was higher than 75 lbs., hence the suggestion to regain the difference in power reduction by improving the economy.

* * *

Lubricant Feed Pressure.—What would be the pressure at the discharge end of a lubricating hose on a boring machine using gravity feed, the supply tank being located 30 feet above the floor?

A column of water one foot in height and having a cross sectional area of one square inch will weigh .434 lbs. As the height of the discharge above the floor will be about 3 feet, the actual head of water will be 27 feet; therefore, the pressure at the machine will be approximately .434 $\times$ 27 equals 11.7 lbs. per square inch.

* * *

Pump Suction Lift.—An engineer friend of mine claims that a pump when equipped with a check valve at the suction end of the intake, and having the intermediate piping flooded by means of a priming apparatus, will lift or draw water vertically and without interruption from an indefinite depth, that is, a depth greater than 34 ft.; for example, say, 40 ft. I claim that under no circumstances, providing, of course, that atmospheric pressure is normal to that of sea level, will a pump draw water from a depth greater than approximately 34 ft. Which is correct, and why?—W. R. H.

The maximum height through which it is possible to move a column of water depends entirely on the pressure of the atmosphere. If your friend could get this first principle of suction lift clearly into his mind he would immediately see the error of his statement and also understand why putting in a check valve will not increase the lift, but rather decrease it. All pumps lift water by exhausting the air in the suction pipe above the level of the water supply. By removing this air, the water is free to rise in the pipe as the result of atmosphere outside pressing on the body of water being pumped. It stands to reason, then, that the water will not rise any higher than necessary to balance the pressure of the atmosphere. In round figures this amounts to 15 lbs. per sq. in., decreasing with the height above sea level. The height of the water in the suction pipe, therefore, will be that which gives a pressure at the lower end equal to the atmosphere. A column of water 1 in. square and 12 in. high weighs 0.434 lbs., so that if 15 lbs. be divided by .434, the result will be the number of feet necessary to give 15 lbs. pressure. $15 \div .434 = 34.5$ ft.

In the case of a plant in a high part of the country, the atmospheric pressure might be only 12 lbs. per sq. in. and $12 \div .434 = 27.6$ ft. The check valve referred to is inserted in the suction pipe to prevent the water dropping back down the pipe should any air enter when the pump is stopped. It is a necessity with centrifugal pumps and reduces the lift by an amount equal to its weight in lbs., divided by its area in square inches, and this again, divided by .434, the answer being in feet.

A CONTRAST

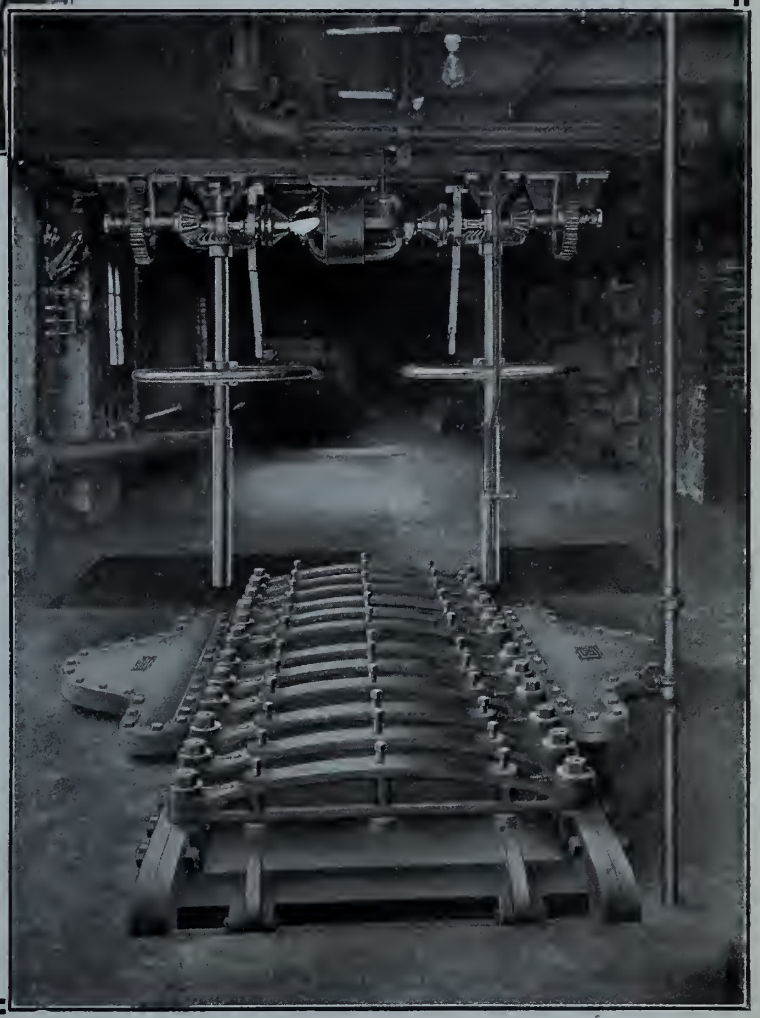
The photograph opposite shows one way of keeping such debris as sticks, leaves, etc., from being drawn into your pumps, condensers and other apparatus.

A diver is engaged periodically to go down under the water to remove the debris that accumulates around the strainer on the inlet of the intake pipe.

The photograph below shows another way of keeping debris from entering your plant via the water intake plan.

A Twin Strainer is used to catch all solids, such as fish, sticks, leaves, twigs, stones, etc., that are carried along in the water. These solids are retained in the baskets of the Strainer, where they can be readily removed at any time without interrupting the flow of water, for when the water is flowing through one set of baskets the other set is out of service.

Motor operated Twin Strainer in 42-inch suction line to condenser—Toledo Railways & Light Company. The motor and operating apparatus is overhead, where it will not be damaged during high water seasons.



Some of the many advantages of the Twin Strainer installation will be readily apparent.

The most obvious one is the convenience of cleaning, which is an assurance against interruptions to the service. The Twin Strainer can be cleaned once or forty times a day, as conditions demand. It can be located in any convenient place inside the plant, where it is accessible at all times.

Twin Strainers will strain water, oil, or any other liquid, and are furnished for either motor or manual operation, in all sizes from 1 to 48 inches inclusive. The basket equipment is varied to suit conditions. Complete information in Bulletin "A." A copy is yours on request.

STEAM SEPARATORS.—II.

WHERE boiler plants are operated without proper attention to water level, or where bad water and overloads are unavoidable, large amounts of water are constantly being passed into the steam main forming

FIG. 11—VERTICAL "WELDERON" RECEIVER SEPARATOR WITH INTEGRAL PIPE EXTENDING THROUGHOUT.

what are termed "slugs" of water which cannot be separated by ordinary separators which deal almost entirely with entrained or suspended moisture. The removal of these slugs is necessary if damage to the plant is to be avoided, and the receiver separator which has been developed to cope with these conditions. Some of these devices consist of regular type separators provided with additional receiving capacity, while others are specially constructed with a view to providing ample capacity as a feature of the design.

Welderon Receiver Separator

Two types of this separator are illustrated, the vertical in Fig. 11 and the horizontal in Fig. 12. They consist essentially of a part of the main steam header, provided with a diaphragm and with inlet and outlet ports, and surrounded by a steel plate body or receiver. This construction is adopted to avoid any reduction in the strength of the steam main, which is carried without break from boiler to prime mover, thus completely eliminating any localization of expansion or contraction stresses, or any shock load due to vibration. Inside the receiver body, the continuous pipe is divided into two distinct portions by a steam-tight diaphragm, which forces steam with its entrained moisture out of the header into the separator body through the inlet port, the area of which is only slightly in excess of the pipe area, thus causing the steam and water to enter the receiver at a very high velocity.

In the vertical type, Fig. 11, the steam enters at the top and passes into the receiver chamber through the inlet port on the right. The inertia of the entrained moisture, due to its greater density, carries it to the bottom of the receiver out of the path of the steam, which circulates around the receiver and passes into the steam header again through the large outlet port shown on the left. Long baffle plates extend at an angle from each side of the continuous pipe, preventing any particles of moisture from being carried from inlet to outlet ports, or from creeping along the pipe.

In the horizontal type, Fig. 12, the steam enters at the left and passes down into the receiver through the inlet port, the entrainment being thereby carried to the bottom, while the steam, in order to pass into the header again, must circulate around in the receiver and rise to the outlet port in the top of the continuous pipe. Baffle plates similar to those in the vertical separator are provided along the sides of the header to prevent moisture from reaching the outlet port. The Elliott Co., Pittsburg, make a complete line of these separators, including angle types, etc., for pressures up to 250 lbs. per sq. in. They are made entirely of steel plates and piping with cast steel flanges screwed on

FIG. 12—HORIZONTAL "WELDERON" RECEIVER SEPARATOR WITH INTEGRAL PIPE AND DEFLECTING PLATES.

FIG. 13—"STRATTON" CENTRIFUGAL SEPARATOR SHOWING INTERCEPTING VANES IN RECEIVER AND CENTRAL OUTLET PIPE.

and welded. The receiver chamber is made in either riveted pipe which forms an integral part of the steam header is in all cases welded to the receiver chamber.

Stratton Steam Separator.

This device is illustrated in Fig. 13 and is designed and constructed to take advantage of the weight and velocity of the water in effecting separation. As shown in the sectional view, the water enters at the right hand side, traveling round behind the vertical outlet pipe, the helical passage causing it to strike the opposite wall at a slight angle, adhering to the wall and forming a thin sheet. This sheet of water flows forward and downward nearly to the bottom of the separator, where its circular motion is stopped by internal ribs, allowing it to collect in the bottom of the separator and flow into the drain pipe.

The current of steam, from which the

BOILER SCALE Never Was NEUTRAL

It is always on the offensive, coating the shells and tubes of the boiler and greatly lowering the boiler steaming efficiency.

DIXON'S PIONEER BOILER GRAPHITE

is flake graphite. Flake Graphite is the "sapper" that undermines and penetrates the scale at the time of its formation.

Dixon's Pioneer Boiler Graphite attacks scale on all sides, rendering it easy to remove when a cleaning tool is used in the ordinary way.

One engineer effected a saving in cleaning cost of 28¾c on each boiler tube by using "Dixon's Pioneer" method.

Why don't you?

water first separates, continues its twisting motion downward to the lower end of the central vertical pipe which leads the steam to the outlet opening. This spinning action of the steam current keeps the sheet of separated water out

FIG. 14—VERTICAL "ELLIOTT" SEPARATOR WITH INVERTED VEE PLATE AND CONICAL FLANGES.

against the wall of the separator preventing it from returning inwards into the steam current after once leaving it.

The vanes in the receiver section of this separator are installed to arrest this rotation of the water so that proper drainage may take place. For convenience in connecting pipe lines, Stratton separators are made in both horizontal and vertical styles, with inlet and outlet openings arranged in any direction to suit conditions. For superheated steam and excessive pressures these separators are of cast steel construction throughout, three different classes being available with varying proportions of storage or receiver space to suit conditions. The Canadian Griscom-Russell

FIG. 15—HORIZONTAL "ELLIOTT" SEPARATOR SHOWING DEFLECTING PLATES AND ISOLATING GRID.

Co., Montreal, are the builders of this separator.

Elliott Steam Separators

This device employs the angular baffle principle with suitable deflection of the steam current. Vertical and horizontal types are shown in section in Figs. 14 and 15. In the former, steam enters at the top and strikes the slanting surfaces of the inverted "V" cast over the central outlet pipe. The openings to the outlet pipe are located beneath the inverted "V" but above the line of its lower edges. To reach these openings, the steam must pass under the edges of the "V" so that the entrained moisture being of greater density, is thrown from the path of the steam to the waste chamber at the bottom and thence to drain. Situated below the "V" are conical flanges which prevent the separated water from creeping up to the steam outlets.

The horizontal Elliott Separator, Fig. 15, is similar to the vertical in that the steam strikes the baffle at an angle instead of in a straight line, resulting in a minimum pressure drop in the separator with more complete separation. On entering at the left, a slanting baffle deflects the steam downward, this change of direction, together with the action of gravity, throwing the entrainment down to the water chamber. A set of inclined bars forms a grating which separates

FIG. 16—SECTIONAL VIEW OF "COCHRANE" SEPARATOR SHOWING SIDE POSTS AROUND BAFFLE PLATE.

the water from the steam chamber, isolating it in a complete manner from the steam current.

Another slanting baffle is placed in front of the outlet passage in such a manner that its upper edge is higher than the lower edge of the left-hand baffle, preventing any escape of entrainment. The designs shown are suited for 250 lbs. pressure, being made of semi-steel and reinforced by webs on neck and body. The Elliott Co., Pittsburgh, make these separators in sizes up to 12 in.

Cochrane Steam Separators

The horizontal type of this separator is illustrated in Figs. 16 and 17, the separating element being a single baffle plate facing the inlet opening, which presents a suitably proportioned surface for the impingement of all the particles of liquid traveling in the current, vertical ribs being provided to prevent side travel of the separated liquid. The baffle plate extends across the diameter of the head, with the exception of two ports having an area exceeding that of the entering pipe. An opening exists be-

tween the baffle plate and the edge of the inlet, so that large quantities of free liquid pour directly into the well. This well is entirely below the course of the current, the underside of the baffle plate being closed over to the outlet and provided with an internal drip pipe.

The ports are situated at the sides of the baffle plate and towards the top,

FIG. 17 — HORIZONTAL "COCHRANE" SEPARATOR WITH SPECIAL RECEIVER CHAMBER.

which, however, is closed for a suitable amount to insure the steam passing round the sides. The vertical form, not illustrated is modified in design and construction to meet the different direction of the current while retaining the same principles of separation. The Cochrane separator is made by the Harrison Safety Boiler Works, Philadelphia, Pa., in a large variety of designs suited to all locations and duties.

TRADE GOSSIP

Bothwell, Ont.—The Town Council are considering installing a waterworks system.

Swift Current, Sask.,—The City Council contemplate purchasing a 615 h. p. oil engine.

Winnipeg, Man.—The City Council will extend the Point du Bois power plant to 100,000 h.p., at a cost of $150,000.

Sudbury, Ont. — The Town Council proposes to spend $7,000 on extensions to its power plant. W. J. Ross is clerk.

Amherst, N.S.—The Maritime Coal, Railway & Power Co., contemplate purchasing pumps, motors and electrical equipment.

Hull, Que.—The city council will call tenders about May 1, for a mechanical filtration plant to cost $170,000. J. P. A. Laforest is engineer.

Chignecto, N.S.—The Maritime Coal, Railway & Power Co., proposes to purchase electric pumps, motors, etc., for to plant. R. J. Bell is general manager.

Coaticook, Que.—Penman's Ltd., propose to erect a power house, construct a concrete dam, and install 180 h.p. turbine and generator. Engineers, T. Pringle & Sons, Ltd., Montreal.

CATALOGUES

Galt Sprinkler Stoker.—The Galt Foundry Co., Galt, Ont., have issued an attractive catalogue dealing with the economic and smokeless burning of coal, including lignite, and at the same time featuring the Galt sprinkler stoker. A full description is given of this type of stoker, and its principal features dealt with in detail, accompanied by numerous illustrations showing the construction and application to various types of boiler. The concluding pages contain some useful engineering data covering evaporation formulae, heat values of coal, feed water calculations, miscellaneous tables, etc. The catalogue also contains instructions for reading the slide rule, accompanied by diagrams. The McNaughton rocking sectional grate bar is also described and illustrated. The catalogue is well gotten up, being printed on coated paper, with exceptionally clear half-tones.

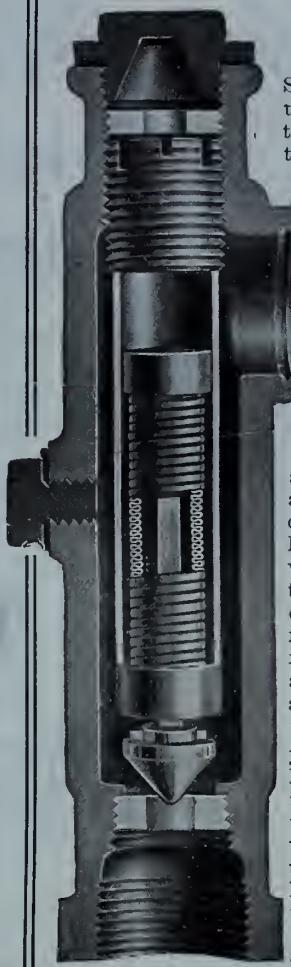
The Steam Trap Sarco Works Hydraulically



Some steam traps of the thermostatic type are operated by ethyl alcohol or other volatile liquids which vaporize. Other traps open and close when a float rises and falls or when a bucket fills and empties.

Work out for yourself how little power traps of this type can develop unless of unusual size. Figure, too, what power is needed to close off quickly and certainly against 100 lbs. steam pressure or 50 or 20 lbs.

Traps of this kind either choke the line and never open freely to discharge but just dribble it through like a cracked valve, or if they open, drain the water, and then, pass a rush of steam before they are able to close against the pressure. **That is where your wasted steam goes.**

The Sarco is quite different. It is hydraulic power which opens and closes the trap. The expansion element is a fluid which at the temperature of the condensation occupies a certain amount of space and at the steam temperature occupies much more space. The difference represents hydraulic power sufficient to close the trap absolutely and unfailingly against any steam pressure up to 200 lbs. You don't waste steam with the Sarco; it can't get past.

You save more than steam; you save in first cost and in repairs. Take a Sarco on 30 days' trial. We would sooner satisfy you by tests than by arguments, but we have both on our side.

"I have about 25 Davis Traps of various sizes in service, the majority of them for 22 years. I will gladly recommend them at all times," wrote H. F. Hustedt, Chief Engineer, Tulane University, New Orleans, when ordering his first repairs.

Possibly all Davis Traps would not last that long without repairs. Much depends on the operating conditions. On some installations they last longer than on others. But all Davis Traps have Tobin Bronze seats and valves—a hard, tough metal from which long service may be expected.

And when these vital parts of the trap do wear out, they may be easily renewed at slight expense.

We make Pressure Regulators . Balanced Valve . Float Valve . Steam Trap . Back Pressure Valve . Exhaust Relief Valves . Stop and Check Valves . Pump Governors . Damper Regulators . Radiator Air Valves . . Emergency Stop Valves.

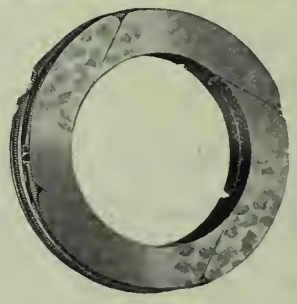
MARTELL PACKINGS MEAN MORE POWER



FAILURE IMPOSSIBLE

Martell packings are in big demand. The call for these superior packings increases day by day, because they never fail. There is little or no friction upon the rod with Martell Packings and no clearance for wear adjustments need be left between the ends. **Sudden failure with the Martell type of packing is unheard of.** It is the ideal packing.

Cut at a tangent to piston rod, and joints on diametrically opposite sides of piston are parallel. This arrangement of the joints of the ring allows the parts to adjust themselves to slight inequality of wear in the diameter of the rod, as they float freely. Therein lies superiority of Martell packings.

It will pay you to try them.

Give Martell Packings a Trial.

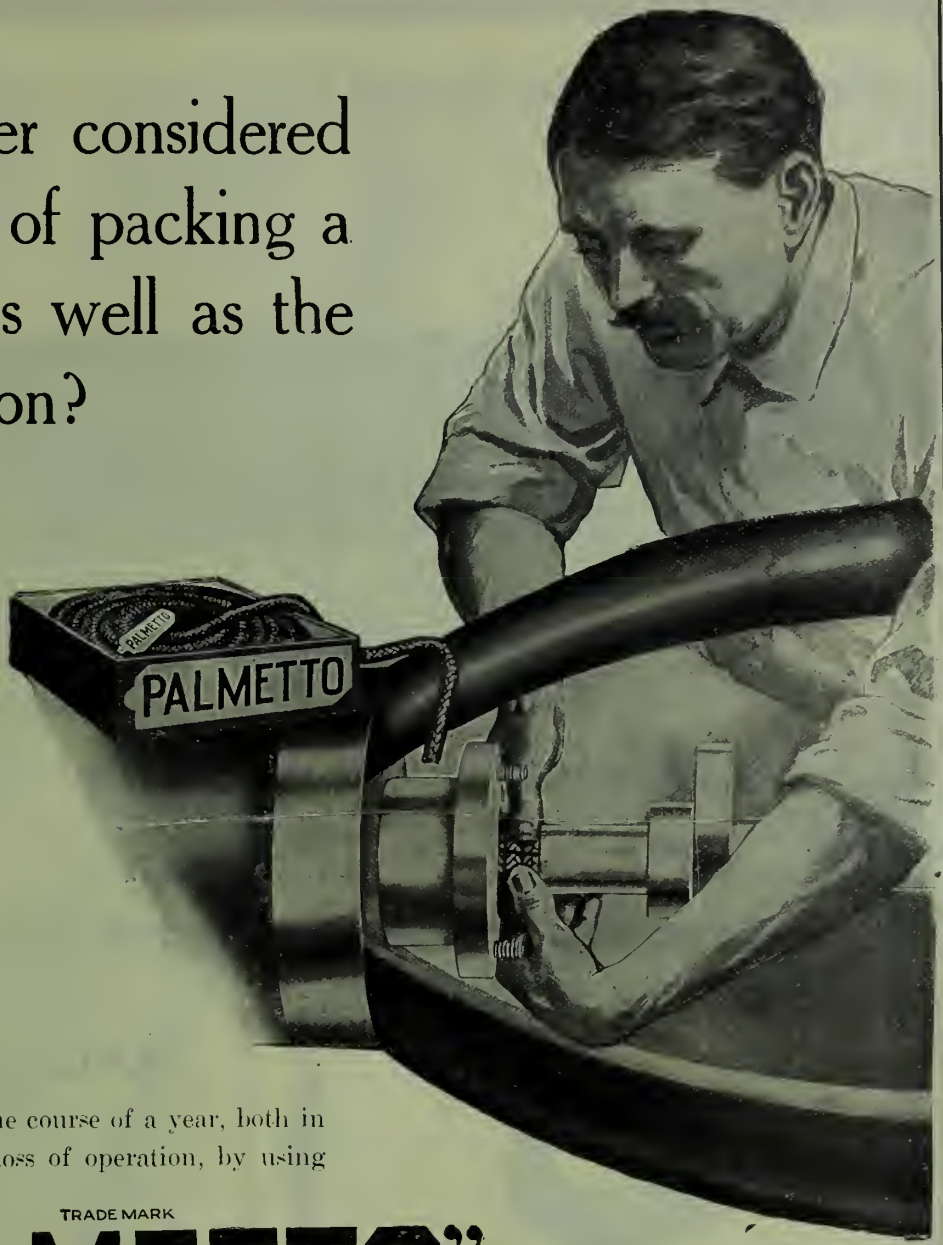
Have you ever considered the labor cost of packing a stuffing box, as well as the loss of operation?



It's a startling amount, especially if you use those packings that have no great lasting qualities and only a low first cost to recommend them.

A great deal can be saved in the course of a year, both in labor cost of application and loss of operation, by using

TRADE MARK

"PALMETTO" PACKING

because it gives a length of service unknown to other packings, due entirely to the grade of materials used and a special process of lubricating each single strand before braiding or twisting. This greater thoroughness costs money, but it pays in the longer life of service.

Let us send you sample of both braided and twist to test under your own conditions. No charge.

The ALBERGER Multi-Head Heater

Stands alone in its freedom from Tube Troubles

The double floating head construction eliminates the dangers of expansion strains to which other heaters are subjected.

COPPER Tubes, Corrugated, eliminate the segregation of materials and splitting, so common with brass tubes.

The helical spiral corrugation gives the water a whirl, which keeps the tubes clean and free from scale, INCREASES HEAT UNITS BY 50% OVER THE STRAIGHT TUBES SO COMMONLY USED.

The Alberger Multi-Head Heater is built on practical lines, which can only be perfected by years of experience.

27 Hard Drives

The solution of the hard-drive problems in every plant depends largely upon the use of proper belting equipment.

Spartan Leather Belting has solved these hard-drive problems in so many plants that we have published a booklet—a record of the experience of others with Spartan Belting.

The twenty-seven hard drives shown in the Spartan Booklet are typical illustrations of the daily performance of Spartan Belting under unusually severe conditions — exposed to water, steam, oil, heat, chemical fumes, and other destructive agencies.

The Spartan Book will interest you, and we want to send a copy because it is pertinent to the solution of your hard-drive problems. May we send it?

S K F Self-Aligning Ball Bearing Hanger with cover removed, showing method of fitting adapter nuts.

USE IT—DON'T WASTE POWER

It doesn't pay to use the old style, profit-eating, plain bearing hangers, when newer, self-aligning, ball-bearing hangers will save from 15 to 24% of the cost of power for operating your line shafting.

What you save in power, not the cost to install, should be the basis for buying all equipment. S K F Self-Aligning Ball-Bearing Hangers insure a saving in power, in lubrication, in maintenance and equipment.

Binding strains, due to out-of-true shafting, are the cause of most of the hot boxes in plain bearing hangers. S K F Self-Aligning Ball-Bearing Hangers automatically adapt themselves to any shaft deflection or spring. No binding strains, no wear, no hot bearings.

Write for our literature giving further information. Complete evidence on request.

GARLOCK
NINE HUNDRED SHEET

Is unsurpassed for superheated steam joints,
It is equally well adapted to air, acids, ammonia,
Or any severe condition where sheet packing is required.
It is made of the highest quality of long fibre asbestos,
And is built up into sheet form under tremendous pressure,
Thus securing great toughness, flexibility and tensile strength.
It is not affected by extremely high pressures and temperatures,
And does not require following up after gaskets have been applied.
Joints can be opened as often as desired without injury to gaskets.
This sheet is furnished in all thicknesses from 1-64 to ¼ inch.
Gaskets of all shapes and sizes can be cut by us from Nine Hundred Sheet.

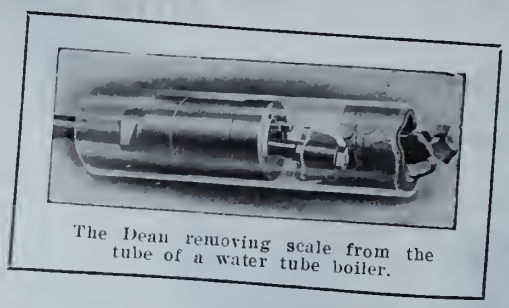
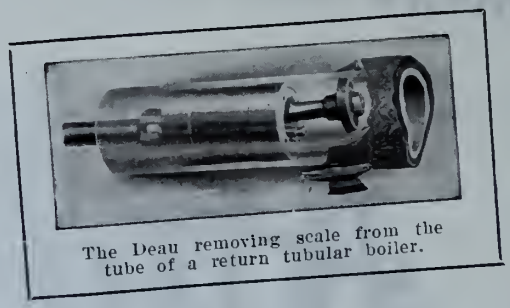
Your Boiler Tubes MUST Be Kept Clean



The Dean removing scale from the tube of a water tube boiler.



The Deau removing scale from the tube of a return tubular boiler.

You cannot afford to adopt halfway methods in ridding your boilers from scale. The tube cleaner that is not removing every bit of the scale is worse than useless because it lulls the engineer into a feeling of false security.

If even a small percentage of the scale is allowed to remain on the tubes, they will become overheated, burn out in spots and put your entire plant in constant danger of a sudden explosion, or serious tube failure.

In competitive tests, the **Dean Boiler Tube Cleaner** has repeatedly demonstrated its superiority as a THOROUGH remover of scale against every method and device made. In many cases, where other cleaners have been put to a severe strain to clean out a small quantity of scale, the **Dean**, operated through the **same tubes** immediately thereafter, has taken out large additional quantities.

Thus, the **Dean** is the final test whereby the results of all other scale-removing methods must be judged.

Why not get a **Dean** first, and be sure of COMPLETE scale elimination?

You may be **absolutely positive** you have no scale, or that your present cleaner is satisfactory. So were many enthusiastic Dean users before they tried this tool.

Try the **Dean** at our expense, and give it a fair chance to show you what you have been missing without it. An agreement to give the Dean a trial implies no obligatiou to purchase. Write to-day for details of free trial offer.

BOILER INSPECTION

The Steam Boiler Act, Chapter 252 R.S.O., 1914, With Amendments Chapter 58—6, George V.

STEAM BOILERS.

All Steam boilers constructed for use in Ontario must be built from designs which have beeu approved and allotted a registration number by the Steam Boiler Branch.

Used boilers, boilers sold or exchanged, and unregistered boilers brought into the Province must be inspected prior to being put into operation.

Notice of repairs to steam boilers, stating the nature and extent of same, must be sent to the Steam Boiler Branch, and should sucb repairs be considered extensive by tbe Cbief Boiler Inspector, the boilers will require to be inspected.

In eacb and every case the inspections must be made by Inspectors authorized to inspect boilers under tbe Steam Boilers Act, who are employed only by the Steam Boiler Branch of the Department of Public Works. Official certificates with the maximum working pressure stated thereon are issued to the owners of the boilers so inspected.

STEAM PIPING.

Drawings and Specifications of all higb pressure steam piping must be approved and registered by the Steam Boiler Branch before any work of installation is commenced. The drawings submitted should show clearly the dimensions and layout of the main steam lines. Full particulars should be given as to the material used in the construction of the piping, and all valves and other fittings used in connection therewith must be of approved make.

Any deviation from the above requirements shall be deemed a violation of the Steam Boilers Act.

All communications in this respect should be addressed to the Steam Boiler Branch, Department of Public Works, Parliament Buildings, Toronto.

HON. F. G MACDIARMID, Minister of Public Works and Highways.

W. A. RIDDELL, M.A. Ph.D., Supt. Trades & Labour Branch

D. M. MEDCALF,
Chief Inspector of Steam Boilers.

Morehead
Back to Boiler
SYSTEM

60,000,000 Tons of Coal Thrown Away Yearly

Over 600,000,000 tons of coal are mined yearly in the United States and Canada. Ten per cent. of that enormous production is carelessly, needlessly wasted. Over Sixty Millions of Dollars are spent each year in producing—nothing, and yet, a mere fraction of that great loss, if properly applied, would save those wasted millions for years to come.

You are contributing to this national waste—but you can stop it.

Steam, after its expansive energy is exhausted, is not through with its job. There are heat units left—live, tangible heat units which were purchased by coal at tbe boiler's mouth.

What Are You Doing With These Heat Units?

This condensation, in other words.

With the Morehead System installed on your steam lines the condensatiou is automatically returned to the boiler—without pumps—and at any temperature. It is the last link from boiler back to boiler—the unused energy is not wasted.

If you would save this ten per cent. and have a clear steam system which drains automatically, write to-day for particulars.

CANADIAN MOREHEAD MFG. CO.
WOODSTOCK, ONTARIO

Paid For Itself in Thirty Days

The chances are that if a device does not prove its worth in thirty days there is little chance that it ever will. But think of this

"Detroit" Systems for Handling Condensation

have records of paying for themselves in thirty days.

Not only will a "Detroit" System pay for itself in a short time, but will continue to save hundreds of dollars a year right in your boiler room by saving fuel.

In your boiler room, as in many others, there is perhaps an adequate provision made to return the condensation.

Better let us send you "Watch Your Condensation."

"CLING-SURFACE! Why, I heard of that twenty years ago! Never took much stock in it, George"
"Well, Uncle, I couldn't get along without it"

Back in '96 and '97, when "Uncle" ran an engine, people took more for granted.

For instance: power lost between engine and machines. With shafting true and bearings oiled, they still lost a lot of power because the belts slipped.

Their belts were run tight. When stretched they were taken up again. This caused friction, which ate up coal and kept the shop busy filling oil cups and cooling hot bearings. So between slipping belts and this friction, 5 to 30 per cent. of the power was lost.

Yet no belt, unaided, could run under full load **without** slipping. If the belts were heavy enough, and the pulleys large enough, a good deal of slip was avoided, but larger equipment required more power to move it.

And sticky belt dressings were as harmful then as to-day. They stopped belt slip for a time, but gummed up both belt and pulley faces; they tore the belts and, often containing rosin or other injurious materials, eventually destroyed them.

It was about this time CLING-SURFACE was discovered. A small beginning: its name did not stare at you in the papers.

Yet CLING-SURFACE soon became well known. People heard of it because it accomplished things.

For tension was doing by *main force* what could better be done by *"persuasion."* And the men behind CLING-SURFACE had found this better way.

CLING-SURFACE stopped the slipping. Since this was the one prime cause for tension, with slipping already stopped, why use it at all?

The Cling-Surface Company preached *slack* belts. Manufacturers who tried CLING-SURFACE discovered a great saving. *No take-up was necessary*, there was no slipping, belts lasted longer, and more power was delivered to the machines with less oil, coal, time and money required than when the belts were run tight.

CLING-SURFACE has grown for twenty years because it has kept on accomplishing things. And it will do the same for you.

We have many interesting booklets: one may describe your conditions. Let us send it to you—with the plan 10,000 firms have found successful. All free.

Remember, use CLING-SURFACE and you won't need belt dressings.

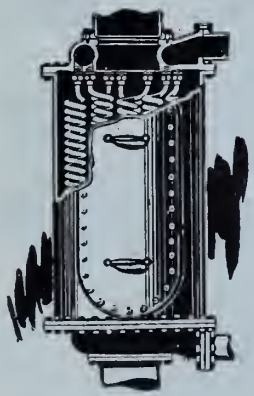
Why not Buy the Best, when in market for Packing?

HOLMES' Metallic Packing

is Guaranteed 3 years

Lasts many times longer. 30 days' trial. Less oil. No cutting. Easily applied to any Steam Engine, Air Compressor or Gas Engine. Satisfaction or no pay. Write us.

Holmes Metallic Packing Co., Wilkes-Barre, Pa.



Reilly Multicoil Feed Water Heater

Has greater capacity per square foot of heating surface than any other type of closed heater. It is simple in construction, light in weight and small in size.

Write for Bulletin No. 210.

OUR LINDSAY WORKS

Boving Hydraulic & Engineering Co., Limited
LINDSAY, ONTARIO

Mention this paper when writing advertisers. It will identify the proposition about which you require information.

COAL FAMINE

You owe it to the Empire that you get the utmost out of your Steam Plant. Your competitors have found that the use of our Boiler Preservatives, Protecto and Protectocoat for interior and exterior use on your Boilers are essential to get same along with Plibrico One-Piece Lining and Plibrico High Temperature Bond for repairs.

PROTECTO
BOILER PRESERVATIVE

Is not a water treatment but has an affinity for hot metal. After clearing your Boiler Plates and Tubes of Scale it forms a protective enamel to which further scale will not adhere. We are willing to give you thirty days' free trial and ABSOLUTELY GUARANTEE PURE STEAM. Prevents foaming or priming.

PROTECTOCOAT
For Coating Your Boiler Brickwork

Fills up present cracks and prevents new ones forming. Will last FOUR YEARS. Cold air penetrates all untreated brickwork and thereby reduces percentage of Carbon Dioxide in your chimney gases from the practical Maximum percentage of 14% to perhaps as low as 3%, entailing a loss per $1000 fuel of $15.00 to $535

Do you know that 1/16th inch Scale on inside of Boiler Shell will waste 13% of Fuel?

ELECTRIC PLANTS. We represent a maker of everything in Vulcanized Fibre products.

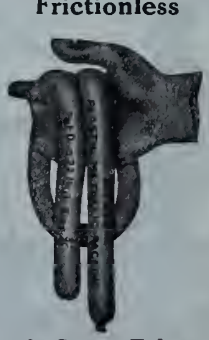
STEEL MILL PACKING CO., WINDSOR, ONT. Established 1899

Practically Frictionless



In Cotton Tubes

If any advertisement interests you, tear it out now and place with letters to be answered.

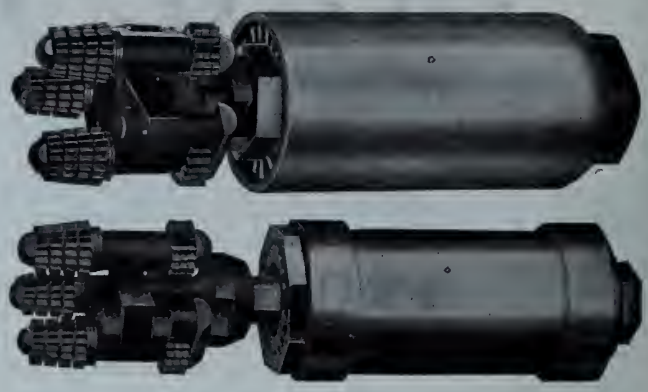
BABCOCK & WILCOX LIMITED

LAGONDA
BOILER TUBE CLEANERS

The latest Lagonda Water and Air-Driven Boiler Tube Cleaners are the most powerful and efficient tube cleaners made. They develop higher speed and greater power than has heretofore been secured with any Turbine Cleaner, and their use will materially shorten the time required in cleaning boilers.

These new Lagonda Cleaners are built for all sizes of tubes, either straight or curved, and they can be driven by water, air or steam.

Ask for Catalog L.



LAGONDA Multiple Water Strainers

The Lagonda Multiple Water Strainer in your water supply main will remove all objectionable solid matter and insure constant and economic conditions of pump and condenser operation. They are easily and quickly cleaned, without interruption of water supply, and take up small floor space. **Ask for Catalog R-2.**

THE POWER HOUSE BUYERS' DIRECTORY

If what you want is not listed here write us, and we will tell you where to get it. Let us suggest that you consult also the advertisers' index facing the inside back cover, after having secured advertisers' names from this directory. The information you desire may be found in the advertising pages. This department is maintained for the benefit and convenience of our readers. The insertion of our advertisers' names under proper headings is gladly undertaken, but does not become part of an advertising contract.

Finest of OILS Greases, etc.

When you feed Non-fluid oil you are sure of this—that it will outlast, measure for measure, any other kind of lubricants, immaterial of price; last three to four times longer than fluid oil; that it will not require the aid of frictional heat before it begins to feed, and will not alter its consistency, summer or winter. These are meritorious claims, but we can live up to the letter of what we claim for Non-Fluid oil.

TRADE MARK REGISTERED IN
NON-FLUID OIL
UNITED STATES PATENT OFFICE

NON-FLUID OIL begins to feed the instant the journal starts to revolve, and it feeds only when the journal turns—only as fast as needed. You are certain of your bearings always being kept well lubricated, and you need have no fear of overheated bearings as long as a particle of this peerless lubricant remains.
It does not drip, spatter or waste. It is a faultless lubricant.

For the Best Oils Try

FRED. SMITH
32 Front St. W., Toronto, Ont.

FREE TRIAL

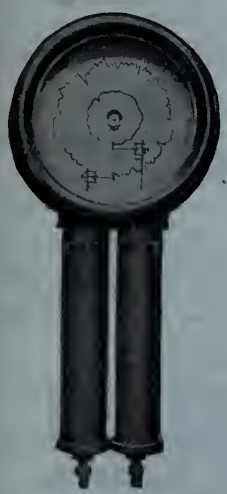
We would be pleased to furnish you with samples of our oil free of charge.

WRITE TO US

We have prepared interesting literature which we will gladly send to you upon request.

UEHLING WASTE METER

COMBINED
CO_2 AND TEMPERATURE RECORDER



Record of CO2 and stack temperature on one chart.

Does your fireman know how much fuel he is wasting? Do you know?

The **Uehling CO_2 Recorder** makes a complete 24 hr. record of your combustion efficiency and the **CO2 indicator at the Boiler Front** holds the fireman responsible.

Get more **Steam** per pound of **Coal** and reduce your annual fuel consumption.

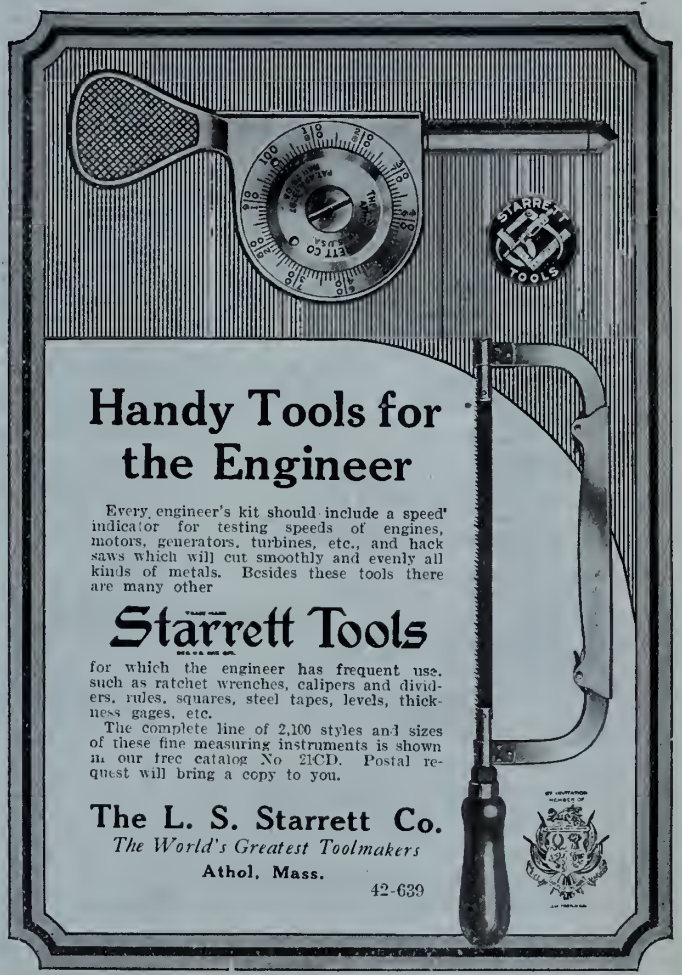
Let us know the number and size of your boilers and coal consumed per year, upon receipt of which information we will be glad to send you full particulars.

CO2 Indicator for Boiler Front

Let us hear from you. We are pioneers in the manufacture of Indicators and Recorders for Power Plant purposes.

Send for our Bulletin No. 110.

Uehling Instrument Company
2008 Empire Building **New York City**



Handy Tools for the Engineer

Every engineer's kit should include a speed indicator for testing speeds of engines, motors, generators, turbines, etc., and hack saws which will cut smoothly and evenly all kinds of metals. Besides these tools there are many other

Starrett Tools

for which the engineer has frequent use, such as ratchet wrenches, calipers and dividers, rules, squares, steel tapes, levels, thickness gages, etc.

The complete line of 2,100 styles and sizes of these fine measuring instruments is shown in our free catalog No 21CD. Postal request will bring a copy to you.

Don't buy that New Electrical Apparatus Just Yet

WE can supply you with high-grade apparatus that has been slightly used and discarded through no fault of its own, at an **immense saving in cost.** For instance, in many cases we take over entire plants simply because of changed conditions such as increased capacity, change of system, etc.

EVERYTHING IS OVERHAULED AND REFINISHED BY US AND **GUARANTEED** AS GOOD AS NEW, BOTH ELECTRICALLY AND MECHANICALLY.

Our catalogs of offerings should be in the hands of every power plant superintendent each time they are gotten out, and it will be worth while for anyone interested in this class of power plant equipment to be on our mailing list to receive **all** offerings.

Nearly all of the principal power, lighting and street railway plants in the United States are our customers.

WRITE FOR OUR LATEST CATALOG of **Power House Equipment, Street Cars, Motors, Hoists, Compressors, etc.**

MACGOVERN & COMPANY, Inc.

114 Liberty St., New York City

The Wrench of 25% Greater Efficiency

TRIMO PIPE WRENCH

Two new features have been recently added to the Trimo Pipe Wrench, namely Nut-Guards, in all sizes, and unbreakable steel frames, in leading sizes.

The Nut-Guards prevent the accidental rotation of the nut while in use.

These improvements add 25% to the usefulness of the tool.

The Trimo Pipe Wrench is made with wood handles in 4 sizes, 6-in., 8-in., 10-in., 14-in. and in steel handles in all sizes, 6-in. to 48-in. inclusive.

All Trimo Pipe Wrench parts are interchangeable.

The inserted jaw in the handle can be readily replaced when worn, thus adding to the life of the tool.

Nut with Nut-Guards

Inquiries from Importers and Dealers Solicited. Send for Catalogue No. 55.

SPRACO

COOLING SYSTEM

Economical — Efficient

For cooling water for Condensers, Transformers, Water Jackets, Ammonia Coils, etc., the Spraco System is preferable. A large number of Traction and Light Companies, Silk and Cotton Mills, Shoe and Leather Manufacturers, Ice and Refrigerating Plants, Mines and Smelters, Steel and Rubber Manufacturers USE "SPRACO" Cooling Equipment. There is a reason—it's Economical and Efficient. The "SPRACO" System of Cooling is supplanting the tower method everywhere on the strength of its merits. For instance—the "SPRACO" requires less power for operation; it is flexible, the tower is not; it uses less make-up water and the initial expense of the "SPRACO" is far below the tower system.

Our catalogue will make it as plain as black and white why the "SPRACO" is preferred. Write to us for a copy without delay.
Our engineering department is at your service at all times.

A Well-Insured Plant

is the power plant of the Ft. Worth Light, Heat and Power Co., Texas. On the inside the coal is stored above the boilers in a Brownhoist Concrete Bin, which time has proved will last as long as the plant and require no repairs. The coal is unloaded on the outside by a Brownhoist Locomotive Crane, which takes it from the cars and places it in storage or puts it through the roof into the Brownhoist Bin. It is safe to say that this plant will have very little trouble, if any, with its coal handling apparatus.

BROWNHOIST

Concrete Coal Bin and Coal Handling Machinery

Write for Catalog S

The Brownhoist Concrete Bin is a steel bin, lined inside and out with concrete. This protects all steel from the corrosive action of the coal or ashes. The oldest one of these bins has been in continuous service for 14 years and has required no repairs. Brownhoist Coal Handling Machines are of various types and sizes for safe, rapid and economical handling of coal. These machines and the bin are described and shown in Catalog S.

Achieving Great Success

The Anderson Pressure Oil Filters are achieving wonderful results in purifying steam and gas engine lubricating oils, gas, gasoline and oil engine cylinder oils, cutting oils used on Automatic Machines and on draw benches, and for drying the moisture from and filtering transformer oils.

Stopped Big Waste

Automobile and gas engine munufacturers are using the Anderson Pressure Oil Filters for oil used in the crank case of the engine when it is given the block or factory test. Before introducing the Anderson Pressure Oil Filters this oil was thrown into the sewer as it was found impossible to clean the oil economically by any other system.

In factories using large quantities of cutting oil on hand-operated and automatic screw machines an Anderson Filter is a necessary part of the equipment.

Don't confuse our Pressure system with the gravity system. We use direct pressure a method based on the same principle used by oil refiners.

BRASS GATE VALVES

APPROVED AND REGISTERED

All Penberthy Gate Valves have the

OUTSIDE BONNET CONSTRUCTION

STRONG WHERE OTHERS ARE WEAK

This Gate Valve

In design, workmanship and material represents the modern, efficient, up-to-date methods of factory production. The best mechanical ideas of the present day are incorporated in this new gate valve, and the defects of faulty design, inferior construction and workmanship of other types entirely eliminated.

The Outside Bonnet

Construction in Penberthy Gates, Globes and Angle Valves is *not* a fad nor a selling point. It *is* mechanically and practically the *correct idea,* and is acknowledged so by leading experienced men in the business.

The solid wedge gate, the packing gland follower, the liberal and even distribution of good steam metal, the fine workmanship, etc., make this valve

Babbitt Metal

Backed by 40 Years of Experience

Hoyt "Frost King"

Scientifically Prepared

There is no guesswork in the manufacture of Hoyt Babbitt Metals. Our "Frost King" brand formula has been prepared by our laboratory experts, who keep close watch that the standard of excellence is always maintained. That's why you can always depend upon its quality.

It is a heavy duty metal and has no peer anywhere. Used extensively for Engines, Pumps, Rolling Mills, Pulp Machinery, Planing Mills, etc.

Order from your dealer—if he can't supply, have us ship you a 25-pound trial box direct.

"NICKEL GENUINE"—Have you tried it? We specially recommend this metal for babbitting dynamos and motors. There's a decided difference between Hoyt Products and other babbitt metals, and you find this fact strikingly exemplified in "Nickel Genuine" and "Frost King." Give them a test—you can't go wrong!

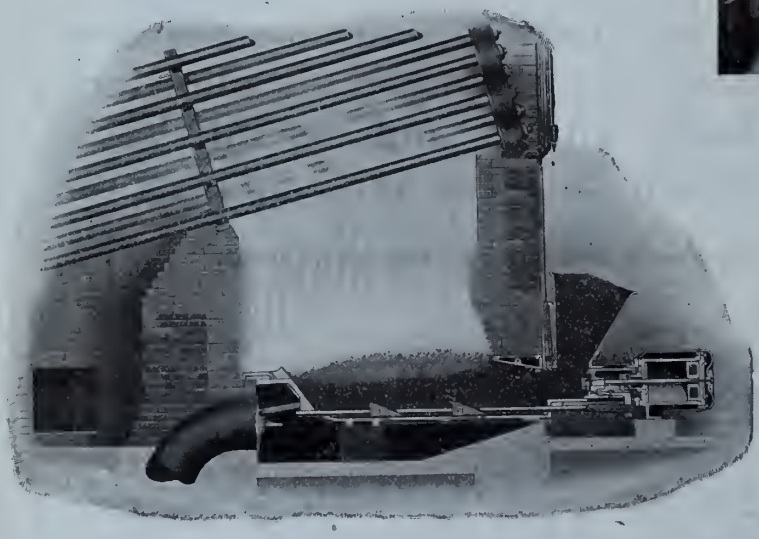
There's No Money Going Up In Smoke with the JONES

UNDERFEED STOKER

In Operation

Where they are installed chimneys never smoke—you lose no money in wasted fuel. This, coupled with uniformity of coal supply, saves up to 25% in fuel.



No Losses Through Grates—There Are None

Simplicity is another of its cardinal virtues. No parts move in contact with fire. Works with very little attention and saves much labor. Does away with a lot of fire worry. Burns less coal and cheaper coal. You get a steady steam pressure, regardless of load.

Would you like to get in touch with some users of this stoker? Write to us.

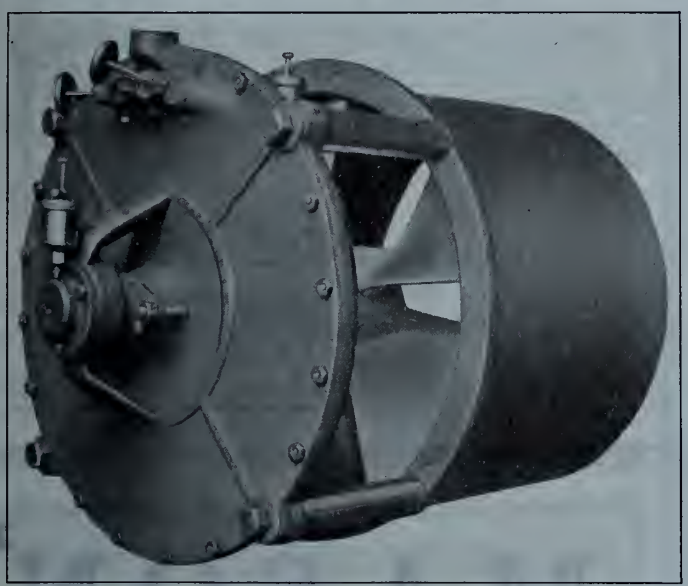
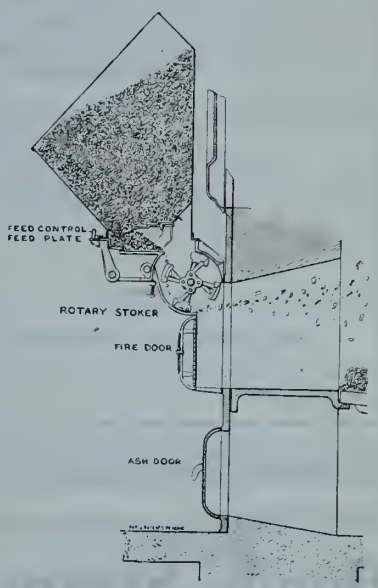
12 Galt Sprinkler 3 Stokers



POWER TURBO-BLOWER.
(Note the individual Nozzle Control). Steam turbine efficiency cannot possibly be obtained by throttling a Globe Valve. The individual nozzle is the only way.

Galt Sprinkler Stokers are the essence of simplicity and high-grade workmanship. They operate with either natural, forced or induced draft.

Our Power Turbo - Blowers are used in every part of the world and can be employed independently or in conjunction with stoker. Cheap—poor coal, peak loads and low smoke stacks have no terror for our equipment.



The stoker mechanically feeds and uniformly spreads any type of fuel in a light continuous stream over the entire surface of your present fire grates. The ideal method of burning coal.

Ask for Catalogues on Stokers, Grate Bars, Blowers, Damper Regulators, Etc.

PEILER'S SERVICE—

THE simple matter of buying goods at one price and selling at another never made a successful business. The ***Element of Service*** is what adds permanence to any organization, and the success of such organization is measured only by its ability to serve. The factor of ***SERVICE***—to the customer—always has been, and is, what has guided us in making connections with manufacturers of power plant specialties.

WE have had many years' experience solving difficult power plant questions, of all kinds and conditions, and the benefit of this experience is yours in dealing with us. If your conditions are not suitable for equipment supplied by us, we do not hesitate to advise what we think will overcome your difficulties.

ON this, and the opposite page, a few of our lines are shown. In our opinion, after long experience, with many tests and trials, they are the best, will stand up the longest, and give the most efficient service, of any that are made on the continent.

Instruments for the Promotion of Efficiency and Economy in the Power Plant and other Manufacturing Departments

"Crescent" THERMOMETERS "Reform"

Power Plant Thermometers—for feed water, economizer, condenser, flue gases, etc., etc., are fully illustrated and described by Catalog Section No. 200. Our "Crescent" Thermometers are featured in a complete line, as are also our "Reform" Mercury Actuated Dial Thermometers which are now so universally used in Power Plants.

Catalog—W200.

GAUGES.

What more close friend of the Engineer than the Steam Gauge? And do you know that we were practically the first to manufacture the Steam Gauge in the world? And in all these years the S. & B. Steam Gauge has retained its reputation of superiority. Catalog—W1.

RECORDING GAUGES.

The Recording Gauge—its value in furnishing written records of pressure, vacuum or draft—is now universally recognized. What progressive Power Plant is without it? If yours is, let us send you catalog No. 100, which will tell you why you should have it—and why you should select the "Columbia."

Catalog—W100

RECORDING THERMOMETERS.

No need of explaining the absolute necessity of recording feed water, economizer, condenser, and flue gas temperatures. Our "Columbia" Recording Thermometer is acknowledged by many prominent Engineers to be "just superior all 'round," Mercury Actuated, Steel Construction. Day and Night Border Charts, Glass Interchangeable Pens, Easy Chart Changing, etc., etc., etc.

Catalog W300 tells all.

TACHOMETERS.

The function of the Tachometer is the measuring of speeds of shaftings, engines, machines, motors, etc., etc. No counting or timing necessary. Just a glance at the dial and you know the exact speed directly in R.P.M. Our line includes Hand Tachometers for portable use, as well as Indicating and Recording Tachometers for permanent attachment.

Pamphlet—W23.

Our Catalogs and Our Service

While our Catalogs will be found wonderfully instructive, we also maintain an Engineering Service Department whose services are at your command—gratis.

REDLINE DIFFERENTIAL DRAFT GAUGE.

A simple, inexpensive, yet invaluable instrument which should be on every boiler. It is an improved pattern of the inclined scale type draft gauge. Pamphlet—W75.

Our line also includes Counters, Engine Registers, Gauge Testers, Steam Calorimeters and innumerable other allied instruments. You should have our catalogs.

ALSO
Indicators
Gauge Testers
Calorimeters
Mercury Gauges
"U" Gauges
Mercurial Barometers

In Old or New Buildings

One of the strongest points in favor of Nonpareil Corkboard is the ease with which it is erected in existing buildings—either concrete, brick, hollow tile or frame. This feature made it possible for the Chicago Cold Storage & Warehouse Company to lease the Soo Line Terminal Buildings, Chicago, Ill., insulate the rooms and secure a large amount of cold storage space in much less time than it would have taken to build a new plant.

Insulating concrete ceilings with Nonpareil Corkboard in the cold storage rooms of the Chicago Cold Storage & Warehouse Co., Soo Line Terminal Building, Chicago, Ill.

In buildings of this type

Nonpareil Corkboard Insulation

For all Cold Storage Rooms

is laid up against the walls, ceilings and columns in Portland cement mortar. A perfect bond is thus secured and no supports or retaining walls are required after the mortar has set. Portland cement plaster is then applied to the surface of the corkboard, giving a sanitary finish. For insulating concrete floors, Nonpareil Corkboard is laid down in hot asphalt and a concrete or wooden wearing surface applied on top.

It is the remarkable structural strength of Nonpareil Corkboard that makes it so easy to install. This, however, is secured with no loss of heat insulating efficiency. Due to the sealed air-cells of the cork and the absence of any foreign binder, Nonpareil Corkboard has the highest efficiency of any commercial heat insulating material.

Literature and sample on request.

Armstrong Cork & Insulation Co., Ltd., 504 McGill Bldg. Montreal, Que.

Also manufacturers of Nonpareil Cork Covering for cold pipes and tanks; Nonpareil Insulating Brick for boiler settings; Nonpareil High Pressure Covering for steam lines; Nonpareil Cork Machinery Isolation for deadening noise of fans, motors and pumps; and Linotile for floors in offices and residences.

Mechanical Refrigeration

In the application of Mechanical Refrigeration in the various trades, we can be of real service to prospective users in suggesting Refrigerating Equipment that will meet the conditions most efficiently and economically.

Our Engineering Department, which is constantly in touch with these problems, is at the service of any one contemplating the use of Mechanical Refrigeration.

Our recommendations are made without prejudice, as we are prepared to furnish the type of Plant best suited to meet the conditions involved.

We invite correspondence on any subject pertaining to the application of Mechanical Refrigeration.

DOORS

For Cold Storage and Freezer Purposes Either Standard or Fireproof

JAMISON'S "JONES" and "NOEQUAL" doors are SUPERIOR because :

1st—Only the best materials are used in their construction.

2nd—We use heavier materials. Result: Longer life and increased efficiency.

3rd—Our doors are built with double and triple seals of contact—others have but one.

4th—Our Automatic Self-Tightening Fastener is the only truly AUTOMATIC and SELF-TIGHTENING Fastener on the market.

5th—Our ADJUSTABLE SPRING Hinges mean the door is always properly seated in the frame, making sagging impossible.

Write for General Catalog No. 7, illustrating and describing both "Jones" and "Noequal" doors, windows, ice doors and chutes, etc.

MARSH and AMERICAN

Steam and Power Driven Pumps and Air Compressors

Marsh and American Pumps are especially adapted for long, hard service because they are *extra heavy* in design and of *extremely rigid construction*. Every unit is built amply strong to withstand 24-hour-a-day service and to stand up under any unforeseen strain which may be placed upon it. Piston rods on the steam pumps are extra large and made of solid bronze. The water ends are equipped with heavy cast bronze removable bushings.

This superior construction not only insures continuous and satisfactory operation, but practically *eliminates expensive shut-downs*. Marsh and American Pumps are the product of over 25 years' experience in the design and construction of high grade pumping machinery. Over 135,000 in actual service throughout the world.

The AMERICAN-MARSH LINE OF CENTRIFUGAL PUMPS is composed of both single and double suction types which are designed for heads up to 125 feet. They are equipped with wide ring oiled bearings and the single suction type has overhanging casing enabling the discharge to be taken at any angle desired.

An Address before the Technical Publicity Association in New York

By Mr. Geo. H. Gibson

THE application of science proceeds at an acelerated pace. The days have about gone by when one good idea would keep a family in business for several generations. No one dare rest content, for as Solomon remarks, "Yet a little sleep, a little slumber, a little folding of the hands to sleep, so shall thy poverty come." Every manufacturer, and particuarly manufacturers of engineering appliances and products, must maintain a constant output of improvements and new developments in order to protect his investment in plant, organization, and good will, and indeed, to stay in business. As has justly been said, the invention of a new machine or process—by some one else—may be as disastrous as a fire, and far more likely to occur.

Moreover, the more progressive, the more advanced, a concern is, the greater will be its volume of new developments and improvements. Inventions breed inventions.

At the same time, the investment of time and money in research and development is a capital risk, that is, the preliminary investigation upon which the design of improved apparatus is based and the provision of manufacturing equipment and organization for turning it out must largely be paid for before the market for it can be developed. It is only by the prompt enlightenment of the prospective consumer, in other words, by educational advertising regarding the applications and advantages of the new article that the loss of time and the waste which always intervene between the perfection of a device or process and its general use, can be reduced.

The introduction of new things is a speculative venture which bars the timid—but for that very reason is highly profitable. Patents more or less effectively insure to the originator a safety zone, protecting him from competition for a limited period that he may have the opportunity to recover his great initial outlay. Advertising, however, is equally useful, since it can shorten the period of loss, conserving for profit-making a greater portion of the 17 years' monopoly conferred by the patent and increasing the volume of profit. *Advertising itself exerts an accelerating influence on technical development, for before advertising, one should have something worth advertising.* Much of the strategy in the competitive selling of engineering appliances consists in originating better methods or designs, or new and improved products.

Good business has been defined as the art of selecting probabilities, and it is certainly true that the greatest successes in the engineering business have come to men who had the ability to do the following things:

(1) Foresee the need or opportunity,
(2) Develop the solution, and
(3) Focus the attention of the public upon the problem and its solution.

AS EXAMPLES, I might mention Edison with the incandescent lamp, Westinghouse with the air brake and alternating current transmission, Hunt with rope transmission, Sturtevant with fans and blowers, De Laval and Parsons with the steam turbine, Babcock and Neier with the water-tube boiler, Diesel with the oil engine, the Wheelers with surface condensers, Hill with technical journalism, Thurston with technical schools, Patterson with the cash register, Herschel with water meters, Kent with his handbook, and many others.

The inertia and prejudice which must be overcome in the introduction of a new device may be illustrated by the experience of Corliss with his variable cut-off, four-valve steam engine. After he had perfected and demonstrated the remarkable savings of his engine as compared with the engines then common in this country, he was still compelled to give the engines away and to take his payment in the fuel saved during the first year's operation in order to make headway.

Many people have the idea that the invention is the important thing. Very few engineering businesses, however, are founded altogether on exclusive and basic patents. They are based rather on a combination of scientific knowledge and business sagacity, with the help of such protection, monopoly or trading advantage as can be obtained from the detail patents which it may be possible to secure as the development of the art unfolds itself. A man may have the germ of a good idea for a successful business, but still nothing that can be protected by a patent, even though patentable improvements will doubtless be discovered upon developing the idea. Nevertheless, the essential factor is the broad judgment or foresight which leads him to take up certain matters at a particular juncture, and not the specific mechanical contrivances by which he may carry out his ideas. *In such cases, the best protection to the idea is advertising by means of which he can promptly get the full benefit of the potential demand for his product before competitors have had time to imitate and develop. Once he has his organization and business well under way, competition will be at a disadvantage.*

ENGINEERING PRODUCTS are purchased almost solely for their utilitarian value. Their usefulness can be weighed, measured or computed in some way, and they are usually purchased with much deliberation, for the reasoning faculties of the people who buy them have been emphasized by technical and business training.

The advertising should arise from and carry forward the general ideas and beliefs of the guiding mind of the business It finds inspiration in new products and the exploitation of new fields. As compared with this broad purpose, the means and methods discussed in books on advertising, such as typography and display, color of ink, quality of paper, etc., are to a degree only incidental—all that is asked of them is that they should do their part in transferring ideas efficiently and not get in the way of the main motive, which is the making use of the spectacular qualities of advancement and improvement and the doing or saying of things interestingly.

The world is run largely on ideas and the dissemination of ideas is the business of the advertising engineer.

Power Plant of the Hudson's Bay Co. Store, Vancouver, B.C.

By A. F. Menzies

From the illustrated descriptive articles appearing in our columns from time to time, covering modern power plant installations, it will be readily apparent that public buildings, institutions, and commercial establishments compare favorably in the matter of equipment, with those more directly auxiliary to manufacturing enterprise. In either case, however, success is largely, if not altogether dependent on the individual, and combined efficiencies of the units installed. That both features have been given prominence here is easily discernible.

THE Hudson Bay Co., justly noted throughout the country for doing things properly, did not trifle with their reputation when they considered the power plant in connection with the recent addition to their Vancouver store. The addition to the building is a sizable affair in itself, while the power plant "down-under" carries the load for both old and new buildings. The original building occupies the corner of Granville and Georgia Streets, while the addition occupies the corner of Georgia and Seymour Streets. Together, the buildings take up the whole frontage of the block on Georgia Street.

Steam is supplied by two 300 horse power Babcock & Wilcox water tube boilers, built at Renfrew, Scotland, and supplied by C.C. Moore & Co. of San Francisco, Cal. The heating surface of each boiler is 3135 sq. ft., and the working pressure allowed by Provincial Rules is 160 lbs. per sq. in. The boilers are arranged in individual brick settings, the bricks exposed in front having white glazed faces. Fig. 1 shows the arrangement of the boilers, the column in the middle of the illustration being one of the supporting columns of the building. Large well lighted pressure gauges are provided, while the water gauges have extension handles enabling the cocks to be blown through and shut off from the working platform. There are two Lukenheimer blow-off valves attached to the mud drums of each boiler, in addition to the blow-off cocks provided by the makers of the boilers.

Oil Fuel

In common with a large number of other power plants on the Pacific Coast, this plant uses liquid fuel. The oil is stored in two 8 ft. 6 in. x 18 ft. steel tanks located below the stokehold floor. The tanks were built by the Vulcan Iron Works of New Westminster, B.C. They are filled from the street level, and are provided with gauges indicating the amount of oil remaining in them. The fuel is supplied by the Imperial Oil Co.

Oil and Feed Water Pumps

From the tanks, the oil is pumped by a pair of 4½ ins. x 2¾ ins. x 4 ins. steam driven, Knowles duplex pumps. One pump is capable of handling the work the other being kept as a stand-by. They are, of course, piped up so that switching from one to the other can be done without loss of time. The pressure in the oil lines is controlled by a Mason regulating valve operated by the oil pressure and operating on the steam supply to the pumps. A by-pass is provided to cut out the regulator when starting up. Before reaching the burners, the oil is heated in a live steam heater and passed through filters installed in duplicate to remove any fine particles of solid matter.

Steam is used for atomization purposes, and the steam and oil pipes can be seen entering the ashpits in Fig. 1. The system was supplied by the Leahy Mfg. Co., of Los Angles, Cal. A check on the oil consumption is provided in the shape of a Worthington piston oil meter which registers in gallons.

FIG. 1. BABCOCK & WILCOX WATER-TUBE BOILER INSTALLATION.

Feed water is handled by a pair of Canadian Fairbanks-Morse outside packed, duplex pumps, each 8 ins. x 5 ins. x 10 ins. The condensate from the exhaust steam heating system is used, and make-up is obtained from the Vancouver City water mains. All feed water is passed through a 3 ins. Venturi water meter made by the Builders Iron Foundry of Providence, R.I. The meter records the amount of water passing, and indicates the instantaneous amount in thousands of pounds per hour. A Standard Speciality Co. feed heater and purifier is provided which heats the feed to from 206 to 210 degs. F.

The feed and other pumps are set on foundations about a foot above the surrounding floor, the visible part of the foundation being faced with white brick, see Fig. 7. The pumps stand in large cast iron drip trays which drain to the sump. As these trays are very large, they enable the floor round the pumps to be kept like the rest of the plant—spotlessly clean. The feed pumps are located behind the boilers, and beside them are a pair of Canadian Fairbanks-Morse 10 ins. x 14 ins. x 12 ins. simplex vacuum pumps. These drain the condensate from the heating system and discharge it into the feed heater. The vacuum pumps are provided with automatic control and a by-pass.

Sump Pumps

As the power plant is considerably below the sewer level, a sump has been provided into which all drains discharge. The sump is kept clear by two motor-driven centrifugal pumps under automatic control. The pumps were supplied by the Byron-Hackson Co. of San Francisco, and are capable of delivering 240 gals. per minute each against a combined head of 25 feet. They are direct connected to 5 h.p., 1100 r.p.m. Westinghouse motors. The automatic control device, worked from a float in the

sump was supplied by the Cutler-Hammer Mfg. Co. of Milwaukee, Wis. As a stand by to drain the sump when the generators are shut down, a 5¼ ins. x 5 ins. x 5 ins. steam driven duplex pump is provided.

The engine room is spacious, being about 36 feet by 110 feet. In it are the two electric generators and the switchboard. The generators are mounted on the crank shafts of Goldie & McCulloch Corliss engines. The latter have 19 ins. x 30 ins. cylinders, and turn up 150 r.p.m. They are provided with double ported Corliss valves operated by eccentrics, separate eccentrics being provided for the steam and exhaust valves. Journal lubrication is provided for by a Richardson-Phoenix oil system. The oil is delivered to the journals through sight feed glasses by a 2½ ins. x 1½ ins. Gardner duplex pump, and returns to the filter by gravity. A thermometer is provided on the filter to give the oil temperature. To care for cylinder lubrication, a Richardson automatic sight feed lubricator is provided and is operated from the valve gear.

Fig. 2 is a view along the engine room while Fig. 3 shows the valve gear side of No. 2 engine. The cylinders are provided with indicator cocks and relief valves at each end. To insure a supply of dry steam to the cylinders, large vertical steam separators are located just above the stop valves. As shown in Fig. 3, Rites inertia governors are provided to care for speed regulation. The governors are belt driven at 250 r.p.m. from the engine crankshafts. All the running gear of the engines is enclosed, efficient splash plates preventing oil from being thrown around.

Engines and Generators

The engine flywheels, one of which is well shown in Fig. 3, are 12 feet in diameter and weigh about 12 tons. They are provided with holes for barring the engines round when overhauling. Fig. 4 is a set of indicator cards taken from one of the engines when running under test, it shows about 400 i.h.p. All the high pressure steam lines in the plant are covered with 85 per cent. magnesia 2 ins. thick, while the low pressure lines have a similar covering 1 in. thick.

Two marble gauge boards are provided, the large one carrying all pressures except steam and exhaust, and the smaller one carrying the live and exhaust steam in connection with the Corliss engines. The gauges are 12 ins. in diameter measured over the dials and are easily read at a distance. They were supplied by the Hohman & Maurer Co. The generators are 1314 ampere 110-220 volt machines built by the Canadian General Electric Co., and are built on the Dobrowsky system. They are capable of carrying a load 25 per cent. cut of balance, and can also carry a 25 per cent. overload for four hours. A commutator with carbon brushes is provided, also two slip rings. The latter have two laminated copper brushes each, which lead to a choke coil; to the middle terminal of the coil is attached the neutral of the three wire system. The choke coil is immersed in oil in cast iron tanks located behind the switchboard. The tanks are provided with radiation fins.

Switchboard

The switch board is well shown in Fig. 5. It has 13 panels two of which are to the left of the illustration and are not visible. The board is of grey marble and presents a very neat appearance. The two generator panels are shown to the left and carry connecting switches and 1600 amp. "ITE" circuit breakers by the Cutter Co. of Philadelphia, Pa., having a tripping range of from 1200 to 2400 amps. At the top of the panels are two Western station ammeters. Voltage regulating rheostats are mounted on the back of the panels with the regularity wheels in front. One main distribution panel is provided serving both the power and lighting load. It is equipped with two Thompson watt-hour meters by the General Electric Co. The clock shown above these meters is, in common with all other clocks in the stores, electrically controlled from a master clock located in the assistant manager's office.

The average winter load consists of 8,000 k.w. hours for power uses, and 12,000 k.w. hours for light, per week. The summer lighting load is, of course, much lower. As no electricity is bought, the stores are entirely dependent on this plant. The remaining panels on the board are for subdividing the distribution. The switches are all by the A. R. Coutts Co. of Vancouver. All the distributing circuits are protected by fuses which are located behind the board, where ample space has been left to get at any wiring. The distribution from the switch board is all carried in metallic conduit. A long rubber insulating mat is provided in front of the switch board, into the pattern of which is worked the firm's name. On a swing panel to the left of the switch-board are located the volt meters. They are arranged so that

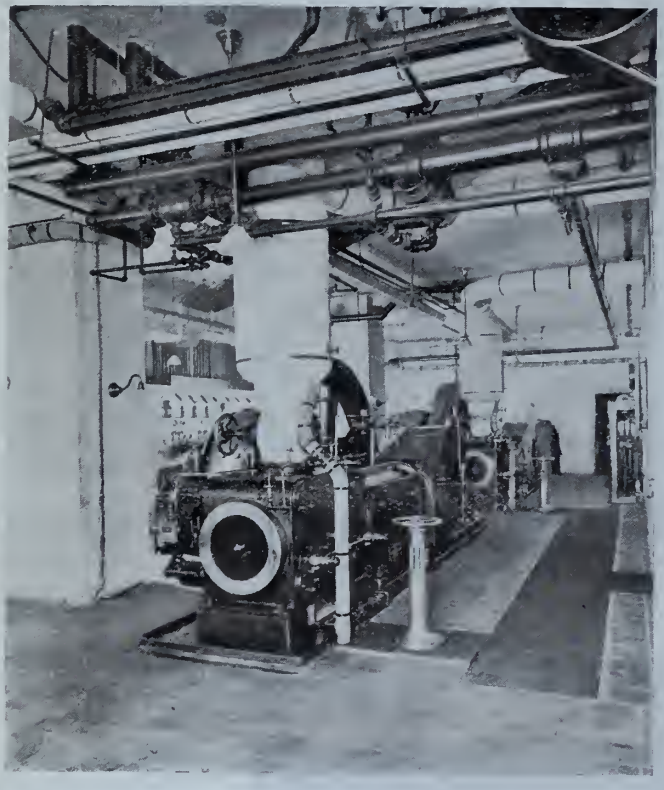

FIG. 2. END VIEW ALONG ENGINE ROOM.

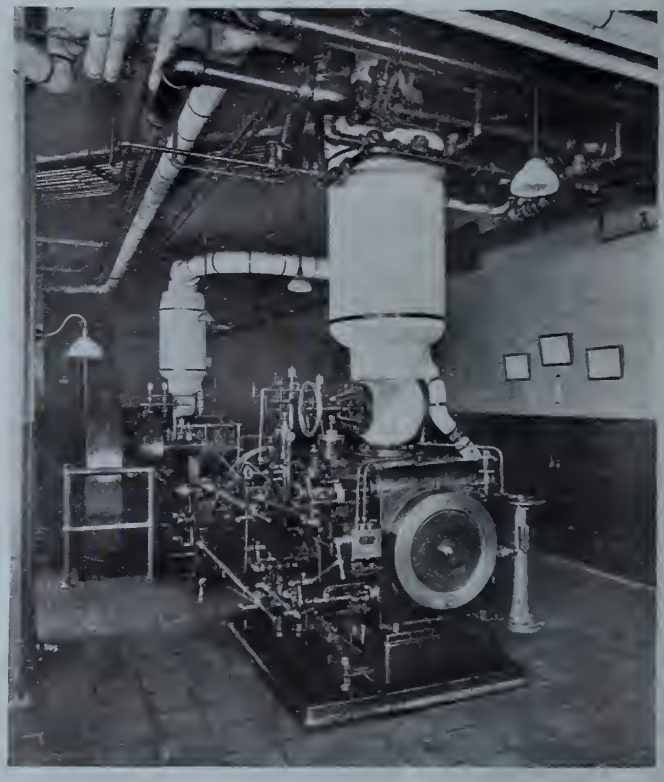

FIG. 3. GOLDIE & McCULLOCH 19 IN. X 30 IN. CORLISS ENGINE.

they can be swung round in order to be seen from any part of the engine room.

For operating signals and other apparatus requiring low tension "juice," a storage battery is provided. The bat-

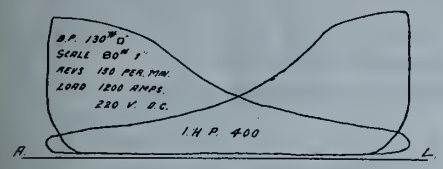

FIG. 4. INDICATOR CARD, 19 IN. X 30 IN. GOLDIE & McCULLOCH CORLISS ENGINE.

tery is charged by a pair of motor-generator sets, taking current at 110 volts, and delivering it at 24 volts. The sets are by the Canadian General Electric Co. and are mounted on a common bed. The shafts are connected by a leather link coupling.

A four tank Bowser oil cabinet is provided for the engine room, each tank of which holds 54 gallons. The tanks are equipped with measuring pumps which can be easily adjusted to deliver ½ pints, pints, or quarts of oil. The pumps are so located that overflow, if any, drains back into the tank. Other useful auxiliaries are a pair of Edison recording steam gauges, one for steam and one for exhaust; a pressure gauge tester by the Ashcroft Mfg. Co.; Crosby steam engine indicator and a Thompson ammonia indicator are also provided, the latter for use with the ammonia compressor.

The main and lower floors are heated and ventilated by warm air, but, above the main floor, the heating is done by direct radiation, using exhaust steam. In the ventilating system, dust is eliminated by drawing the air through water sprays. Two Sirocco air washers using city water are provided. There are four Sturtevant ventilating fans each direct connected to a 12 h.p. 245 r.p.m. Westinghouse motor. The fans have a capacity sufficient to completely change the air in the buildings every fifteen minutes. A temperature indicator by the Taylor Instrument Co. is provided and located in the engine room. From it the temperature of any part of the building, or that of the outside air can be ascertained by closing a switch.

A Blaisdell vacuum cleaning system is installed, the pump being 14 ins. x 10 ins. It is belt driven by a 15 h.p. variable speed motor. The pump and motor are on a common bed plate, and the short belt drive is provided with an idler which ensures good belt contact at the motor pulley. The pump suction valves are mechanically operated by an eccentric on the crank shaft, while the discharge valves are automatic.

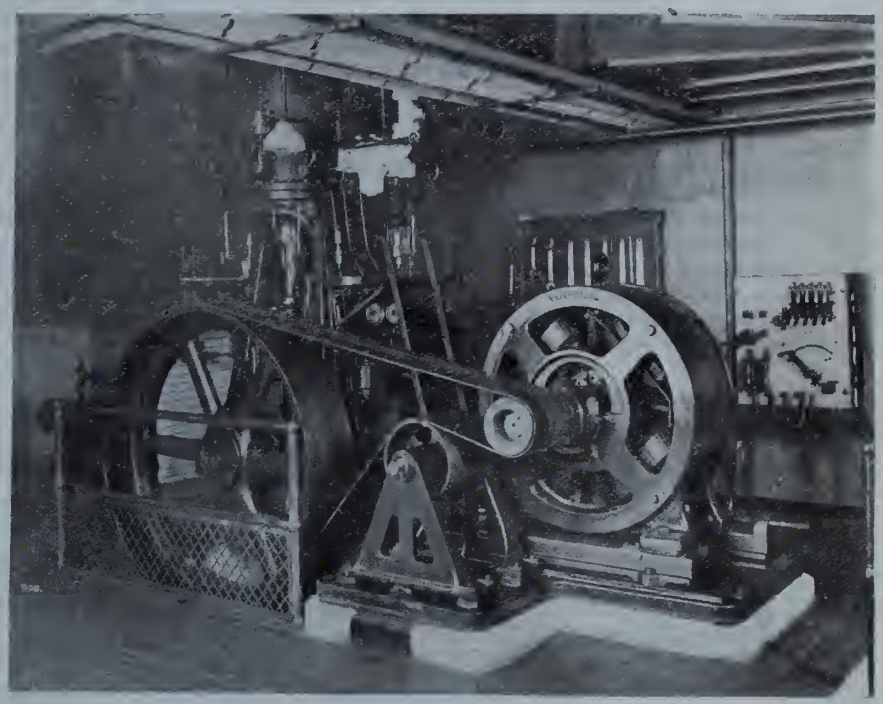

FIG. 6. REFRIGERATION EQUIPMENT DETAIL.

FIG. 5. MAIN SWITCHBOARD SHOWING INSTRUMENTS AND OPERATING EQUIPMENT.

Refrigerating Equipment

To provide refrigeration for various purposes in the stores, a 20 ton ammonia compressor is installed. It was supplied by the Frick Co., of Waynesboro, Pa. The compressor is a vertical twin cylinder, single acting machine 9½ ins. x 10 ins. and is driven about 55 r.p.m. by a variable speed Westinghouse motor. The motor has a speed range of from 450 to 900 r.p.m. It is mounted on a sliding base on the common bed plate. The compressor and motor are well shown in Fig. 6. The driving belt is of leather and is of "Duxback" brand.

A noteworthy feature shown in Fig. 6 is the spanner rack. These racks are provided near each machine and all special tools for that machine are kept in them. A glance shows if any are missing and there is no time lost looking for tools when they are wanted.

The ammonia is condensed in a double pipe condenser, the fittings of which were also supplied by the Frick Co. The condenser is shown to the left, on Fig. 7. It is supported on three solid piers. The space between one pair of piers is used to house the ammonia storage cylinder. The refrigeration is carried out on the cold brine principle. The evaporating of the ammonia taking place in a Carbondale Brine Cooler, shown in the centre distance of Fig. 7. The wood legged tank to the right is the brine storage. The cold brine is circulated by a pair of 2 ins. two stage centrifugal pumps having a capacity of 75 gallons per

minute against a head of 138 feet. The pumps were made by the Union Steam Pump Co. and are direct connected to 10 horse power, 1700 r.p.m. Westinghouse motors. The brine pipes are very heavily insulated with cork. The thickness of the insulation can be judged from the apparent size of the pipes in front of the Carbondale brine cooler.

On top of the building there are two 20,000 gallon tanks, one for the sprinkler system and the other for domestic uses, toilets, etc. All overflow water is sent up to these tanks by two motor driven three stage centrifugal pumps built by the Byron Jackson Co. One of these pumps is shown on the extreme right in Fig. 7. Each pump has a capacity of 100 gallons per minute against a head of 220 feet. The pumps and motors are on a common bed and the shafts are connected by a leather link flexible coupling. The motors are 15 h.p. and turn up 1800 r.p.m.

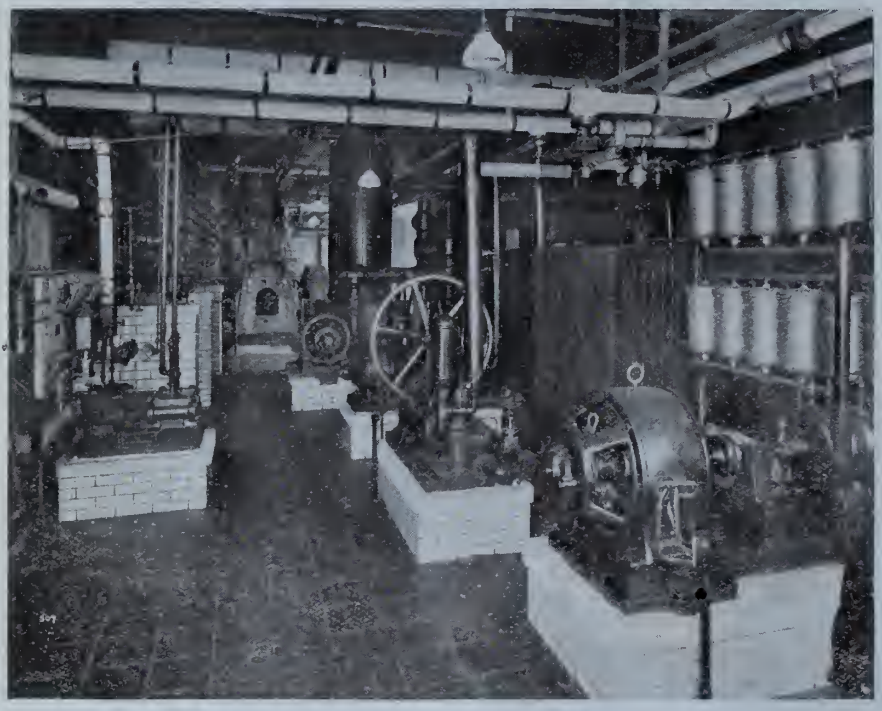

FIG. 7. PUMP ROOM, SHOWING EQUIPMENT DETAIL.

The Grinnell sprinkler system is installed in the old building, while the addition is fitted up with the International system. In addition to the sprinklers a number of hydrants are provided for fire protection. Extra pressure is provided for the hydrant lines by a four stage Byron Jackson centrifugal pump which is capable of delivering 500 gallons per minute against a 200 foot head. The pump is driven by a 50 h.p. Westinghouse motor turning up 1400 r.p,m, The motor is provided with a sheet steel cover to keep it dry in case of fire when water would probably be coming down from the floors above.

The store is provided with a pneumatic cash transfer system. This system is operated by means of two Connersville blowers having a capacity of 17 cu. ft. per revolution. The blowers are belt driven at 120 r.p.m. from 15 horse power, 1100 r.p.m. motors. The suction and exhaust pipes in connection with the blowers are of sheet steel 14 ins. in diameter. Compressed air is used for intensifying the pressure on the sprinkler system storage tank, and also for operating elevator doors, etc. It is supplied by a pair of automatically operated compressors, each rated at 50 cu. ft. of free air per minute. The compressors, twin cylinder single acting machines, were built by the Westinghouse Traction Brake Co., and are motor driven. The motors are 12 h.p., and are built into the machines with a gear drive, making a very compact outfit. The motor speed is 1100 r.p.m. which is reduced to 183 r.p.m. at the crank shafts..

Burke Horwood & White were the architects in charge of the building, while P. R. Moses of New York was the consulting engineer. The power plant is in charge of W. L. Vaughan who is assisted by S. A. Conrad and J. E. Wilson.

COMBUSTION IN HAND-FIRED FURNACES

THE fuel in most types of furnaces acts primarily as a gas producer. With a 6-inch fuel bed the oxygen in the air rising through the grate is all used up in combustion in the first 4 inches from the grate. At a distance of 4 inches from the grate the carbon dioxide content of the gases has reached or passed a maximum of 10 to 16 per cent. and begins to drop. At the surface of the fuel bed the gases contain no oxygen, only 6 to 8 per cent. of carbon dioxide and 20 to 32 per cent. of combustible gases. The composition of the gases is practically independent of the rate of air supply. The larger the quantity of air forced through the fuel bed, the faster the fuel burns or gasifies, but the ratio between weight of air supplied and weight of fuel burned remains constant at about 7 to 1. In general the temperature in the fuel bed is the highest at 3 to 5 inches from the grate, which is also the point of maximum carbon dioxide content.

Fuel Bed Thickness

As most of the oxygen is consumed in the first 4 inches of the fuel bed, it is not necessary with the ordinary rates of combustion to run a fuel bed thicker than 4 to 6 inches in order to obtain a high carbon dioxide and a low oxygen content in the flue gases. The rate of combustion or gasification of coal depends on the amount of air that can be passed through the fuel bed. The thicker the fuel bed the higher is its resistance to flow of air through it and the less air can be passed through with a given chimney draft. A thick fuel bed, therefore, reduces the rate of combustion and thus reduces the capacity of the boiler.

A thick fuel bed is further undesirable because it increases the tendency of the coal to form troublesome clinker. Perhaps the only apparently defendable excuse for carrying a thick fuel bed is the fact that the chances of burning holes in the fuel bed are reduced. A skillful fireman avoids holes in the fuel bed by firing frequently and placing coal on the thin spots. A claim that fuel beds can not be kept in good condition if carried thin is a confession of neglect and lack of skill. A fuel bed is understood to be only the layer of incandescent and freshly fired fuel and does not include the layer of dead ashes and clinker on the grate. The ask fuses in the upper layers of the fuel bed, and as it sinks it solidifies 2 to 4 inches from the grate. In most cases the fusion occurs in a reducing or partly reducing atmosphere, consequently in studying fusibility of ash the determinations should be made in a partly reducing atmosphere.

As at the surface of the fuel bed the gases contain 20 to 32 per cent. combustile gas and practically no free oxygen, to obtain complete combustion additional air must be introduced over the fuel bed. This statement is true of all the fuels, including coke, tested by the Bureau of Mines, Washington. D.C. As a general statement, about one-half of the 15 pounds of air used to burn 1 pound of coal in a boiler furnace is supplied through the fuel bed; the other half must be supplied over the fuel bed.

Combustion of coal is a chemical combination of the combustible ingredients of the coal with the oxygen of the air. The chief combustible ingredients of coal of economic importance are carbon and hydrogen in various combinations. Average commercial coal contains about 82 per cent. of carbon. and about 4 per cent. of hydrogen available for combustion. Air, without which the coal could not burn, contains approximately 20 per cent. of oxygen and 80 per cent. of nitrogen.

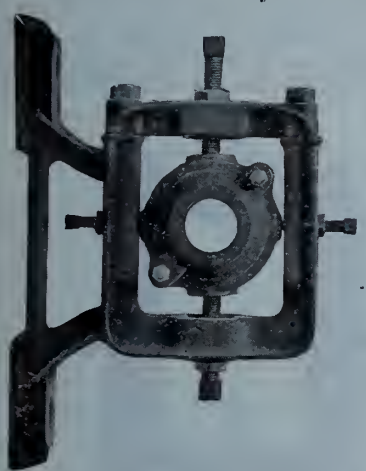
Power Transmission Section

SAVINGES MADE POSSIBLE BY BALL BEARING HANGERS

By C. T. R.

EXHAUSTIVE tests in manufacturing plants have demonstrated tbat transmission losses due to friction of plain bearings amount to from 20 to 40 per cent. of the total power used in tbe plant. The purpose of this article is to show how the major portion of this loss can be eliminated by the use of self-aligning ball bearings.

Shafts in cast iron, babbitt or bronze bearings become "set" if tbe shafting is idle for any length of time. Tbe oil is pressed out of these bearings, and it is extremely difficult to start the shaft from rest. Again, when the bearings are operating at normal speed, rubbing friction is constantly consuming



BALL-BEARING POST HANGER.

power at a sacrifice of efficiency. Self-aligning ball bearings are designed to eliminate all these difficulties.

In self-aligning ball bearings tbe starting friction is no greater than tbe running friction. This is a very important fact, for, as it is not necessary to provide for heavier starting loads, a much smaller motor may be used. Again, the rolling friction is practically uniform from rest up to very higb speed. On this account they start with a minimum effort, and operate at all times with the highest possible efficiency.

When hangers are equipped with self-aligning ball bearings, the selection of a motor for shop drives reduces itself to the problem of providing for normal machine power consumption only, without the necessity of providing for tbe heavy overload capacity usually required to "start up." For example: if machines in the shop normally require 250 horse-power to drive, and an additional 50 horse-power is consumed by the line shaft in distributing this power, a sav-

BALL-BEARING PILLOW BLOCK.

ing of 50 per cent. of the power required for tbe line shaft will reduce the total power required by 25 horse-power, i.e., 10 per cent. of the total. With a motor costing approximately $9 per horse-power, there will be an initial saving of approximately $225 in the motor cost.

So far, we have considered only the saving in power and the consequent lower first cost of the driving motor. In addition to the saving in power, which alone is a sufficient item, there is also a considerable saving in lubricant. It is necessary to lubricate double row, self-aligning ball bearings only three or four times a year. The lubricant supplied to each bearing at such times is considerably less than is generally sup-

SECTIONAL VIEW, BEARING IN HOUSING.

plied a babbitt bearing several times a month.

This economy in lubrication results from the fact that the liberal lubricant chamber around the bearing is sealed on both sides to insure the retention of the lubricant, as well as to protect tbe bearings from intrusion of shop dust, grit, etc. The seal is such tbat the lubricant cannot leak out or creep along tbe shaft to the pulleys and belts, a feature wbich preserves the efficiency of the belts and eliminates the uncleanliness and annoyance of oil.

In plants where the transmission is exposed to dust, moisture and grit, self-aligning ball bearings will give the best of service. The dust-proof housing is oil tight, excludes foreign matter and holds the lubricant. Cement mills, foundries, woodworking shops and machine shops are some of the places where htse bearings can be used to good advantage. Most shafting in plain babbitt bearings is run at speeds from 100 to 400 r.p.m., and if run at higher speeds, it is necessary to lubricate the bearings frequently to avoid hot boxes.

Self-aligning ball bearings may safely be run at double or triple this speed,

BALL-BEARING DROP HANGER.

the size of the pulleys being cut down as formerly. A considerable saving in the cost of pulleys can thus be effected; or, when operating at increased shaft speed, by keeping the main line pulleys close to their former diameter (thereby increasing the rim speed), narrower and lighter belts can be used. Working along these lines, it is possible to effect savings which will equal the difference in cost between self-aligning ball hangers. Thus, it is possible to secure the highly efficient ball bearing equipment at the same initial cost as the plain bearing equipment.

Instances are frequently encountered where a manufacturer is using all his available power and is even operating his engines and boilers or motors at a

heavy overload. He constantly faces a complete breakdown of his plant. In order to add more machinery it will be necessary for him to invest considerable money in an extension of his power-generating equipment. However, by using self-aligning ball bearings this would be unnecessary in many cases, while in others, the additional requirement would be on a much reduced scale.

We are indebted to the S. K. F. Ball Bearing Co., Toronto, for the accompanying illustrations.

FRICTION AND LUBRICATION OF SHAFTING

Vulcan Staff Article.

MACHINERY and shafting in general, including the fittings, principally comprises details which are in sliding contact with each other. If clean metallic surfaces are placed in absolute contact, and one part slid over the other, excessive friction is developed, by which serious resistance to motion is caused, and the surfaces are wasted by abrasion. In order to minimize frictional resistance and to prevent wear (or to reduce this to a negligible amount), the use of a lubricant is adopted in such a manner as to effect a definite separation between the surfaces, although, at a glance, they appear to be in contact with each other. The lubricating agents commonly adopted are oil or grease in various forms and conditions; also soap, tar, and other fluid, semi-fluid and more solid substances.

Lubricant Action

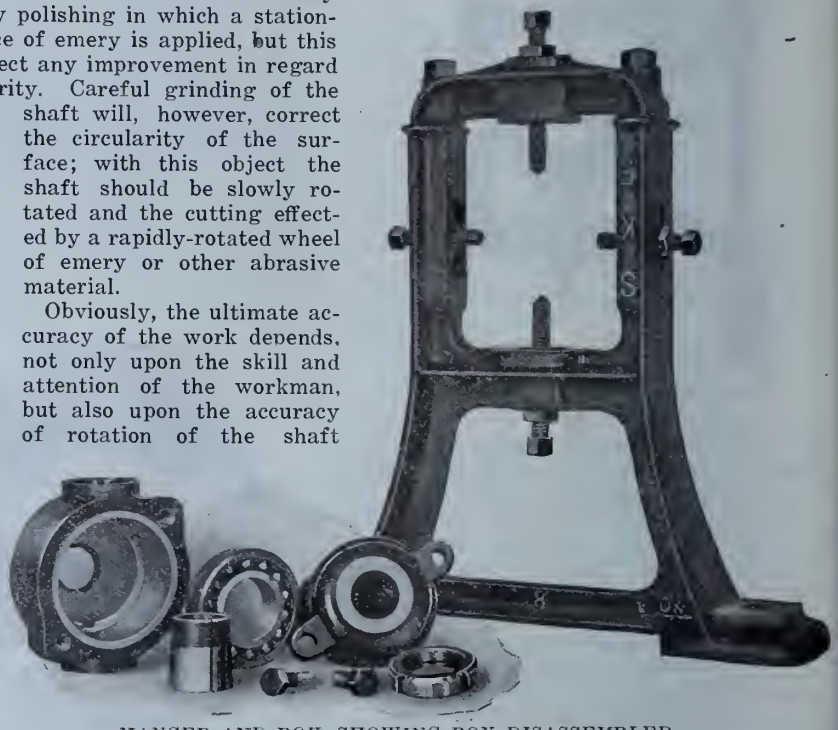
The film of lubricant acts in much the same way as a series of infinitely small friction rollers. Obviously the accuracy of action, and, therefore, the efficiency of the result, must depend upon the perfect accuracy of the fitting of the mechanical surfaces in each particular case. In connection with a shaft rotating at a high speed, the two surfaces, convex and concave, must be true to circular form. In practice a plain shaft, as left by the turning tool, is not necessarily circular in cross-section, for various reasons connected with the operation of turning in the lathe. Such a shaft is invariably finished by polishing in which a stationary surface of emery is applied, but this cannot effect any improvement in regard to circularity. Careful grinding of the shaft will, however, correct the circularity of the surface; with this object the shaft should be slowly rotated and the cutting effected by a rapidly-rotated wheel of emery or other abrasive material.

Obviously, the ultimate accuracy of the work depends, not only upon the skill and attention of the workman, but also upon the accuracy of rotation of the shaft (preferably upon hardened and ground centres), and upon the truth of rotation and freedom from vibration in connection with the revolving grinding wheel. The matrix or bearing surface by which the shaft is supported should also present an accurate surface, and where the matrix is of hard material it is necessary to adopt measures corresponding to those applying to the shaft. If, however, bearings of soft white metal are adopted, the surfaces of these will adjust themselves by wear in a comparatively short time. When the operation of correcting the circularity by grinding is properly conducted, it incidentally removes a thin coating of metal, which may be said to have been loosened or adversely affected in the principal process of turning. This metal may be compared to an infinitely minute coating of valvet, the minute fibres of which are all bent away in the same direction. By the process of grinding, a superior surface of solid metal is presented whereby the frictional resistance to motion is reduced and the vibration or deflection of the centre line of rotation is eliminated.

Ground Bearings for High Speed

All bearings which are required to rotate at a high speed should be finished by grinding, as a point of necessity. The amount of advantage to be thus obtained in connection with parts which rotate at a low speed may be correspondingly small; but in all cases, great care should be devoted to an adequate degree of accuracy in the bearings. The bearings of a crank shaft, even if working at a low speed, are of sufficient importance to call for finishing by accurate grinding in all cases in which the contractor possesses the necessary appliances. In the absence of such appliances, the shaft is finished by turning and polishing, and some engineers are strongly of opinion that better results are obtained when these operations are performed with a shaft rotating in the same direction as it will rotate in its ultimate working position. This can only be explained on the assumption that the incipient fibres of metal are pressed aside by a tool, and

ADAPTER BEARING, DEFLECTED VIEW.



HANGER AND BOX, SHOWING BOX DISASSEMBLED.

left somewhat in the manner of a pile on a velvet cloth, as above referred to. Consideration of the foregoing points will assist in the study of any question affecting the resistance to rotative movement in shafting. The same may be extended to movements of surfaces of revolution of any kind, and also to plane surfaces.

Direct Frictional Resistance

The amount of direct frictional resistance in pairs of solid bodies, as developed when one object is laid upon the other and slid along it, is proportionate to the magnitude of the force by which the one is pressed or held against the other. In the case of dry unlubricated surfaces, the frictional resistance is about one-fifth of such weight or force. This quantity is generally given in the form of a fraction, as .20, which is applied to the amount of pressure at right angles to the surface. This fraction is termed a coefficient of friction, and it is largely reduced by the use of a lubricating agent. For all metallic surfaces, plain or revolving, and which are lubricated by anointing with tallow, lard, or olive oil before placing in contact, the coefficient of friction has been found to be from 0.07 to 0.08. In good modern practice, the majority of revolving and sliding surfaces are lubricated with a copious supply of thin oil, whereby the coefficient of friction is reduced to its lowest limits. About the year 1884, B. Tower made a large number of experiments in which the coefficient was brought down to 0.001 or 0.002, equivalent to a fifty-fold reduction upon the results above given.

Types of Shafting Lubrication

The two principal types of shafting lubrication now adopted are by pump supply and by rings. In pump supply, means are adopted for the collection of oil which leaves the bearing, also to conduct it to a pump for return to the bearing so that the oil is used over and over again indefinitely. In the simple case the used oil may be collected in the bottom of a wall box, or equivalent position. This should be effected with due regard to the following points:—

(1)—The collection should be complete without leakage or distribution by spray or otherwise. Most frequently some loss is incurred by faulty fitting or arrangement. This loss is objectionable from an economical point of view. In a closely-proportioned detail, it may involve the exhaustion of the supply of oil whereby risk of heating and serious damage may be involved. Oil which thus escapes is very likely to cause damage to walls and foundations, and almost certainly it presents a most objectionable eyesore.

(2)—The means of collection and pipes by which the oil is conducted to the pump should be so arranged as to avoid deterioration of oil by dust from the atmosphere. Dust from the atmosphere may be excluded by the adoption of screens of sheet steel, well fitted against both sides of the wall box, and such other openings as may exist. These must be arranged for convenience of opening or taking apart whenever required.

(3)—It is an advantage to have a short break in the delivery pipe by which the current of oil can be placed under observation at any time. For this purpose it may very well be protected by a glass tube. This gives an opportunity for observing the quantity of oil delivered, and its condition with reference to clearness and limpidity.

(4)—The collectors should be thoroughly cleaned by scraping and brushing down to the bare iron, so that all surfaces with which the oil can come in contact are clean; also this operation should be extended to any upper surfaces from which foreign matter can possibly drop. This applies more particularly to sand, which, although it may be comparatively soft and easily removed, is often allowed to remain. The same observation, however, applies to hard sand, as this is liable to soften by extended contact with oil, and, moreover, it is at all times liable to detachment by a blow with very serious results.

Ring Oiling

Ring oiling is effected by the use of a ring or endless chain of greater diameter than the bearing. The top brass and the cap of the bearing are arranged so that the rings can lie upon the revolving shaft, and can be driven by frictional contact when the shaft is rotated. The whole arrangement, including the bottom shaft, must be so designed as to allow the ring or chain to be rove along the shaft into its position; or alternatively, the ring or chain may be arranged for division into two parts for placing in position or removing therefrom. The bottom brass is sometimes divided into two to clear the ring, but this is not necessary or desirable. The ring or chain must possess sufficient weight to originate an amount of friction sufficient to drive the ring with its load of adherent oil, and also to overcome the resistance of oil in the oil well. The oil well should provide sufficient depth of oil to load the ring without dipping so deeply as to pick up the dregs of oil. In connection with this type of apparatus, the necessity for removal of dirt, sand, and foreign matter generally, as already explained, applies to the fullest possible extent. The cap of each bearing should be so arranged as to give a good view of the oil when passing over the top of the bearing. Here also the view is necessary for estimating the quantity and condition of oil.

A certain amount of cloudiness develops in oil after repeated use. This is principally due to wear of surfaces, but its quantity should be negligible except as to a short period after starting up new work. The amount, of course, depends principally upon the degree of excellence in the fitting and adjustment of bearings whereby the amount of frictional resistance is minimized. Oxidation by atmospheric influence should be kept in mind, although it does not frequently occur with the use of good oil; but, on the whole, it is better to avoid exposure of any considerable amount of oil surface to the air.

Choice of Lubricating Oil

In the choice of lubricating oil, one of the most important conditions is the degree of completeness with which the frictional resistance is eliminated by the use of the oil. As a rule, oil which is supplied for lubricating purposes is not of a character which is prone to oxidation, but an occasional consignment may give much trouble by gumming, which arises in this way. Excessive frictional resistance is often due to excessive viscosity in the oil, which is equivalent to a deficiency in the degree of fluidity most appropriate to the work of the particular bearings in question, and chiefly with regard to the pressure per square inch to which the bearings are exposed and to the surface speed adopted. A heavy load requires an oil of high viscosity. High speed may facilitate the use of thin oil, and thereby effect a reduction in frictional resistance, but any deficiency in the workmanship is attended with greater trouble in case of the high speed.

Cases have been recorded in which a change of oil has been attended with an increase of 15 to 20 per cent. in the amount of power which is required to drive a given quantity of machinery. If the engine happens to be very closely proportioned to its work, the steam and fuel consumption will rise in a proportion distinctly greater than the increase in the horse power. Obviously, if the additional power is confined to the shafting it may be disclosed in the most striking manner by the indication of the friction load, with all machinery stopped. It is, however, improbable that an increase in the power of the amount stated can be incurred on shafting alone, but there is every reason to believe that it is often incurred in connection with the total load, on account of machinery with the hundreds of thousands of spindles which are used in textile mills.

Power in excess, which is above referred to, is in every case represented by heat which is generated in strictly accurate proportion to the amount of power consumed, and such heat is distributed over the details in proximity to the surface upon which the resistance is developed. Therefore, careful observation by touching the bearings will, in many cases, suffice to show a distinct difference between the moderate heating due to ordinary work, and the excessive heat due to inordinate resistance to motion in bearings, spindles, and other surfaces which are subject to friction.

Excessive resistance is, moreover, often caused by defective alignment of bearings, either originally or as consequent upon subsidence in the ground and foundations. Such variations in alignment may be found either in a horizontal or a vertical direction. Experience appears to show that few large works have the bearings accurately adjusted either as to lines or levels. In this connection a hypothetical example may be taken in a shaft of 4 in. diameter, which is carried in bearings placed at 10 ft.

centres, and which is deflected by ¼ in. from the accurate line in the middle of a length of 20 ft. This bearing will have an additional load of 394 lbs. imposed upon it by the deflection, and a further counter-load of 394 lbs., which latter is principally upon the two bearings next adjoining the one in principal question, or a total abnormal pressure across the shaft of 788 lbs.

At a speed of 200 revolutions, and with the full coefficient of .075 as appertaining to bearings which are occasionally oiled by manual attention, the loss by abnormal friction becomes serious, amounting to .375 horse-power. This loss is, however, very frequently exceeded by reason of the stiffness corresponding to the shafts of larger diameter, and also by reason of greater derangement of centres. In a recent case, a serious error of this kind was discovered in the second motion shaft of a large engine, as to which evidence shows that the derangement had existed and caused much trouble during many years.

Erection and Correction of Shafting Bearings

In connection with the erection and the subsequent correction of the bearings of shafting, the first point is in regard to the alignment in ground plan, as to which any fair mechanic will have no difficulty in stringing a line along beneath the shaft and straddling the shaft with a plumb-line on each side of the shaft near to each bearing. The levelling of the shafting is attended with more difficulty than the horizontal alignment, on account of the fact that special levelling apparatus is required. Ordinary levelling from one bearing to another by an ordinary straight-edge and with a hand-level is attended with difficulty and loss of much time, and is, moreover, not reliable in its results.

The majority of careful millwrights when engaged upon levelling over long distances use a water level, the principal elements in which are a long flexible tube and a terminal piece at each end in the form of a glass tube. The apparatus is filled up with water so that the surface shows in both tubes at the same level. This apparatus is very clumsy for use in most favorable conditions. It is difficult to ensure accurate transference of levels from the surface of the water in the tubes to the actual bearings of the shaft, and it is most essential that all possibility of air locks, bubbles, or other interruptions in continuity of water in the tube and connections should be fully assured.

In all ordinary cases, the use of an ordinary dumpy level, as used in survey work and heavy engineering construction, gives, however, much better results, and in a more convenient manner than any water level. In the majority of dumpy levels, the cross lines are given by thin spider webs, which are difficult to adjust in position and are liable to frequent fracture. The writer calls to mind one case, in a work of importance, in which the cross line was carried away by a strong gleam of sunshine and the work consequently stopped, causing great inconvenience. Experience of this kind will account for the reluctance of millwrights in adopting the use of such a level. In good modern instruments, however, the cross lines are given by ruling upon a glass plate, which is beyond comparison more reliable. The use of a dumpy level for this purpose is generally conducted by giving a mark for each bearing, all such marks being accurately placed at the same level. The quantity of shafting and bearings is usually much greater in a weaving shed than in other situations, but the shafting in such positions is, however, more flexible on account of its comparatively small diameter. Very great improvements have been effected by correcting the shafting on results obtained in this way.

VALUE OF INSTRUMENTS IN POWER PLANTS

INSTRUMENTS to show whether a plant is operated efficiently are generally wanting. In boiler rooms from 10 to 20 per cent. of the fuel, and more in some of them, is wasted chiefly from lack of indicating devices to detect losses. Every boiler should have a draft gauge and, if possible, a steam-flow meter. No boiler room should be without some form of gas-analysis instrument and flue-gas thermometer or pyrometer. Too much guessing is done in the average power plant, which is, in part, responsible for the miserable results obtained. Few plants pay particular attention to obtaining economic combustion; many operators have no idea what high CO_2, low CO, and other such expressions mean. Hence it is not surprising that there are boilers operated at 40 per cent. efficiency.

An automatic CO_2 recorder has a great moral effect upon the fireman, and numerous boiler plants can thank this apparatus for a large saving in fuel consumption. While it is of great value in any boiler plant, plants having a variable load with hand-fired boilers, and those having chain grates, stokers, etc., especially need this apparatus, since in them CO_2, ordinarily, is found the lowest.

The steam-flow meter on each boiler in connection with proper interpretation of the pressure through boiler gas passages, is also of great value and, with intelligent, trained men in charge, even preferred to the CO_2 recorder.

The common differential draft gauge is also importnt, for, when properly connected, it will tell whether the boiler is being operated at, below, or above rating; and whether the fuel bed is too thick, or dirty, or full or air holes. The draft readings must, however, be intelligently interpreted, and they seldom are. Fed operating engineers know the real value of the draft gauge.

Flow meters are quite important in testing recipracating pumps for their displacement efficiency, and centrifugal pumps for decrease of efficiency from wear of internal parts. When a plant is installed, provision should be made in various steam, water, and air lines for connecting a flow meter, and if none is put up permanently, a test meter should be kept to check the performance of various departments or single units of power machinery and the keeping up of

$$\text{the } \frac{\text{output}}{\text{input}} \text{ ratio.}$$

PROPER FEED WATER

MUCH heat is wasted by dirty boilers, and the cost of cleaning in most plants is considerable. Using distilled water as boiler feed should be advocated whenever possible. In large plants the condensate from the condensers of the main units could be used to condense the exhaust steam from the auxiliaries, and all the make-up water obtained from a cultiple-effect evaporating system, or flue-gas evaporators working under vacuum. In other plants more attention should be paid to treating the feed water.

Properly treated feed water will not only improve the efficiency of a boiler as a heat absorber, reduce the cost of boiler cleaning and its repairs and increase its life, but will also greatly increase its safety, since most boiler explosions and accidents can be traced to unsuitable boiler feed water.

City boiler inspection departments, with the aid of water departments, could be of great aid to the operating engineers in the particular cities by keeping them informed as to what treatment the water requires to make it suitable for boiler feed. Much good could also be done by boiler insurance companies, not only to the engineers and power plant owners, but also to themselves, if they had chemists to inspect samples of feed water and advise proper treatment.

EXPLOSIONS IN BOILER FURNACES

AS the gases rising from the fuel bed contain 20 to 32 per cent. of combustible gases, it is not difficult to understand that under the right conditions an explosive mixture can be formed that might cause an explosion violent enough to injure the fireman. An explosive mixture can be formed in a boiler furnace in either of the two following ways:

1—With a tight setting and the fire doors completely shut so that no air is entering above the fuel bed, the furnace and the setting are filled with a combustible gas. If then the fire doors are suddenly opened a large volume of air is admitted into the furnace and mixes rapidly with the combustible gas. Under such conditions the combustion of the gases may be so rapid that it assumes the violence of an explosion.

2—With the fire doors wide open the furnace and the setting fill with air. If then a shovelful of slacky coal is spread over the fuel bed and the fire doors are quickly closed, the large volume of combustible gas rising from the freshly fired coal forms an explosive mixture with the air in the setting. An explosion may follow which is strong enough to blow the fire door open and even lift the hood noticeably from its seat on the setting.

Observations on Safety Valves for Marine Boilers*

By E. F. Maas

The various elements of marine boiler safety valves which have to do with successful operation are considered. Seven typical valves are discussed and illustrated. Many suggestions of practical value for the grinding and repair of safety valves are embodied, these being the result of observations made by the author on valves under working conditions, and on repaired valves in the laboratory. The subject is pertinent to our shipbuilding revivals.

THE purpose of this article is not give a complete description of the design and working of all marine safety valves to be found on the market to-day, but to analyze some of the characteristics of the working parts of the more common types, to indicate their advantages and the difficulties experienced with them, and to point out helpful methods in repairing and improving old valves. The paper presents the results of observations made on valves under working conditions and during tests of repaired valves in the mechanical laboratory. In the case of one valve, not yet upon the market, the statements are based upon experience gained from work on other valves, and on a somewhat incomplete report of laboratory tests of this valve. This test was not witnessed by the author. Each of the seven figures gives, not a complete view of a valve, but a partial section only, this section showing such parts as come within the scope of the paper. It is assumed that the working of these safety valves is familiar to every reader, as well as the nomenclature of the valve parts. No general explanation of them, therefore, is given.

Fig. 1 represents a valve of a somewhat obsolete design probably not made by any manufacturer to-day. This type

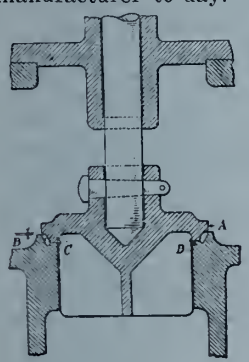


FIG. 1. OLD TYPE OF SAFETY VALVE.

is still to be found, nevertheless, in many of the older ships, and should be considered. Fig. 2 shows a later type of valve having an attachment for adjusting the blow-down, a feature indispensable in a modern marine safety valve. Fig. 3 is practically the same as Fig. 2, the main difference between the two being in the design of the blow-down adjustment. Fig. 4 represents one of the latest and most successful designs on the market at the present time. In Fig. 5 is shown a valve which has not yet fully emerged from the experimental stage, and to the knowledge of the author is not yet offered for sale as a marine safety valve. Figs. 6 and 7 show modifications made to valves of

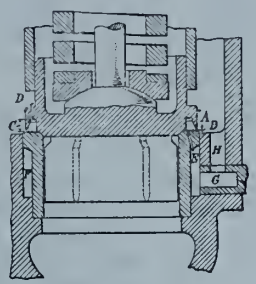

FIG. 2. LATER TYPE OF VALVE WITH ADJUSTABLE BLOW-DOWN.

the type represented by Fig. 3, these modifications having been applied during the repair of these valves in order to fit them for further service, after their original working adjustment had been destroyed through long service or neglect in maintenance. The particular features discussed in the article are:

(a)—Valve seat, flat or beveled, and its tightness.

(b)—Pop of valve, amount of simmering before pop, and height of lift.

(c)—Closure of valve and chattering at closure.

(d)—Blow-down of valve and methods of adjustment.

(e)—Discharge capacity.

(f)—Overhaul and adjustment of old valves and improvements made at slight expense.

Valve Seat

A glance at the figures will disclose two valves with flat seats (Figs. 1 and 5), the other five having beveled seats. While this might indicate that the beveled seat is the more common, the relative advantages of each type are strongly supported by manufacturers of the two types. The experience of the author has been that a flat seat is just as easy to grind-in and make tight as a beveled seat, and that the flat seat is more likely to stay tight. On account of the distortion of the valve seat which will result from a slightly uneven expansion or from spring of the material under high pressure, the tightness of a beveled seat is seriously affected, and the more so the greater the bevel, if by bevel we understand the angle between the valve seat and a plane perpendicular to the center line of the valve.

On the other hand, a flat seat will remain steam-tight even after a considerable distortion has taken place, provided that the valve has been carefully ground to its seat in the first place. It should be borne in mind that the valve and seat are in contact only along a very narrow strip, in the case of either flat or beveled seats. For equal lifts of the valves, a flat seat will give a greater discharge capacity under certain circumstances, as will be discussed later, a fact which will weigh in favor of the flat seat, for some designs, at least. It has been argued that a beveled seat, especially where the bevel is considerable, about 45 deg., will more easily rid itself of particles of scale or other foreign matter between the valve and its seat. In this connection attention should be called to the prevalent custom in marine practice of attempting to tighten the valve on its seat by turning it by means of the valve stem. Such practice usually has an effect directly opposite to that desired. A better way is to lift the valve from its seat by the easing gear and thus blow away the scale or other matter. A steeper bevel than 45 deg. is inadvisable for a steam safety valve, as the tendency for the valve to stick on its seat is too great and may produce disastrous results. It is significant that while only a few years ago most safety-valve specifications

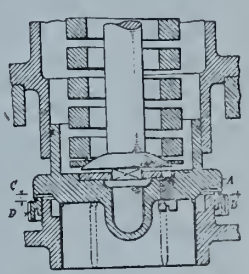

FIG. 3. MODERN SAFETY VALVE WITH ADJUSTABLE BLOW-DOWN.

called for seats beveled at an angle of 45 deg., specifications of to-day, notably those of the U. S. Navy Department and various State Boiler Rules, do not require it, indicating that a transition from 45 deg. to the flat seat seems to be under way. It is the author's opinion that such a change is for the better.

Pop of Valve

By "pop" of a safety valve is meant its instantaneous rise to almost full lift after the first tendency to move from its seat, or what is known as simmering,

*From a paper presented before the American Society of Mechanical Engineers, New York, December, 1916.

has taken place. A clean-cut pop is most vitally necessary in a successful safety valve. Without pop there will be a prolonged simmering of the valve as soon as the pressure has been reached for which the valve has been set, and the unduly prolonged simmering will soon score both valve and seat, particularly if the steam is superheated, thus producing a leaky valve. The pop of the valve in Fig. 1 will be determined by the diameter of the flange A, the amount of the distance B, and, to some extent, by the shape of the surface C. It is assumed, of course, that the valve has been ground to its seat and made tight. To design a valve of this type that will give a satisfactory pop, therefore, requires previous experience regarding the relations of these three variables, otherwise some experimenting must be done. When this valve is refaced and reground, it is also of utmost importance that the original conditions of the working parts be restored. Gauges for the original shape of both valve and seat, and the proper distance between the two, should be furnished the machinist repairing the valve, otherwise a misfit is liable to result and an uneconomical valve produced. A valve of this type requires a very long spring in order to give a satisfactory lift, on account of the small overhang of the flange A over the seating surface of the valve D, which limits the available additional lifting force required after the valve has started from its seat.

In the valve in Fig. 2, the pop will depend on the diameter of the flange A, the amount of the distance B, the depth C of the main pop chamber, and the size and number of the holes D. Of these four items, A and D are determined by the manufacturer of the valve, and, if rightly proportioned in the first place, need never be changed. Items B and C are both variable, however, with the wear and refacing of the valve and seat. In this valve it is desirable to have the lip A wear down in the same proportion as the valve and seat. As this is very seldom the case, however, there arises the necessity for adjusting these features when the valve is overhauled. It should be noted that the depth of the pop chamber does not influence the pop as much as does the distance between the flange lip and the valve bushing. The former need be checked only roughly, while the distance B must be absolutely correct. An approximate value for B is 0.01 in. for the average size of marine safety valve.

The pop in Figs. 3 and 6 is decided by the three items, size of flange A, distance B and depth of pop chamber C. In these respects the valves are similar to the valve of Fig. 2, the remarks about which will apply to Figs. 3 and 6. One difference, and an important one, is that the distance B can be adjusted after the valves are assembled, by means of the blow-down ring D. Thus, it would seem as if the necessity for the very close machining of the lip A in overhauling these valves would not exist. Such is not always the case, however, as the adjustment of the distance B for a satisfactory pop may interfere with the adjustment for the desired blow-down. This will be explained in more detail later.

In the valves of Figs. 4 and 7, the pop is dependent upon the size of the flange A, the distance between flange and

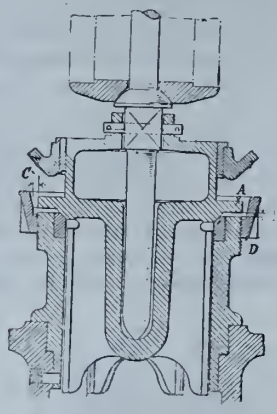

FIG. 4. RECENT TYPE OF MARINE SAFETY VALVE.

valve seat B, and the width of the ring-shaped opening at C. This difference between the two valves prevails, however, that in Fig 4 the main deciding feature is the distance B, by reason of holding the ring area C comparatively large, whereas, in Fig. 7, the pop will be determined mainly by the distance C, which is just large enough to let the valve flange A clear the inside of the adjusting ring D. Therefore, in overhauling the valve of Fig. 4, strict attention must be paid to the distance B in order to bring it back to its original value, by means of a cut from the wider side of flange A in case either the valve or its seat have been refaced, thereby lowering the valve and decreasing the distance B. In the valve of Fig. 7 only a rough check of distance B need be made. A suitable valve for this distance in an average-size valve is 3/16 in. The width of the ring area C has been fixed once in making the valve parts, and need never be changed in overhauling this valve.

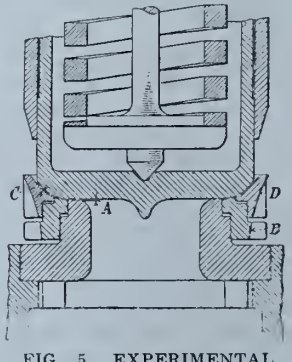

FIG. 5. EXPERIMENTAL VALVE.

In Fig. 5, the pop depends upon the distances A and C, which can be regulated by means of the adjusting rings B and D. The inner ring should be screwed very close to the valve disc, but not touching it. The outer ring furnishes the greater part of the additional lifting force required after the valve has started from its seat.

Simmering

The reduction to a minimum of the period of simmering before lift, which is very essential to the successful working of any safety valve and to the length of its useful life, can easily be accomplished in all the valves of Figs. 3 to 7 if the proper care is exercised. In the valves of Figs. 1 and 2, as previously pointed out, the reduction of the simmering is mainly a question of design and original adjustment, unalterable after the valve has been set up.

Lift

It is known that all safety valves will give their highest lift at popping, the sustained lift being less than this by from 10 to 25 per cent.. The average lift of a 3-in. or 4-in. valve is about ⅛ in. To increase this lift without interfering with the blow-down or resorting to abnormally long springs is a difficult matter. In order to obtain the maximum lift, the valve spring should be made to contain as many turns as possible within the space available for it.

Closure

In order to prolong the life of a safety valve, it is necessary that its closure be accomplished with the minimum amount of shock. When a valve comes down on its seat each time with a heavy blow, both valve and seat will soon be distorted, and the valve will start to leak. For obtaining a large discharge capacity, a high lift is desirable, but this becomes a detriment if the closure is accompanied by shock. In this respect a valve with a beveled seat is generally inferior to the one with a flat seat, as the flat seat affords more of an opportunity for the steam to form a cushion at the moment of closure. Especially is this the case with the valve shown in Fig. 5, there being an excellent steam cushion between the valve disc and the inner ring B for checking the descent of the valve. Another valve which seems to give an easy closure, although having a 45-deg. beveled seat, is the one shown in Fig. 7. It is to be regretted that on neither of these valves are there available data on the length of their useful service without repairs upon which to base a more reliable conclusion regarding this feature of the valve closure. As previously mentioned, both of these are new types of valves and not yet fully tested out in service. The tendency of a valve to chatter at closure is generally caused by too small a blow-down.

Blow-down

For adjusting the blow-down, or difference in steam pressure under the valve at popping and at closure, there are two different systems represented in the valves shown. Before analyzing these two systems, it should be mentioned that in the valve of Fig. 1 there is no adjustment of the blow-down. In this valve, therefore, the amount of blow-down desired will have to be decided on in advance, by previous experience from similar valves, proportioning the

valve flange and the spring as well as the shapes of valve and seat so as to give the desired blow-down.

The arrangement in the valve of Fig. 2 for adjusting the blow-down is one probably familiar to most steam engineers. When this valve discharges, part of the steam passes through the holes E drilled in the bushing and into the chamber F, generally termed the secondary pop chamber, but more properly called the blow-down chamber. The only exit from this chamber is through the bushing G and the passage H communicating with the discharge space of the valve casing. By turning the bushing G and locking it in different positions, the size of this exit passage for the steam can be restricted, thereby limiting the amount of steam passing through the holes E, and so regulating the pressure under the valve lip A. Of course, the holes D in the valve flange will have a similar influence on the blow-down. The size and number of these holes are generally proportioned for a minimum blow-down of, say, 4 lbs. A smaller blow-down than this should not be attempted in any safety valve as it only shortens the life of the valve and produces a tendency to chattering, as previously mentioned, with no additional advantages in the working of the valve.

In all of the valves of Figs. 3 to 7, the adjustment of the blow-down is accomplished by means of the adjusting rings D. Screwing these rings up will increase the blow-down and screwing them down decreases it. The shapes of these rings should be noticed. The rings of Figs. 4 and 5 are especially adapted to give a minimum obstruction to the flow of steam and so increase the discharge capacity of the valve, both being excellent shapes. It has been especially claimed for the ring of Fig. 5 that in conjunction with the lower ring B it has the effect of reducing the lifting force at very low lifts and increasing it as the lift increases. This is a most desirable feature in any safety valve.

The ring D of Fig. 7 has been designed and tried out as an improvement on valves of the type shown in Figs. 3 and 6. It has already been pointed out that in these valves the main feature determining the pop is the distance B, also that the position of the ring D will determine the amount of the blow-down. Thus it will be seen that there are two factors to be considered in determining the proper position of these adjusting rings, and that each of these factors may require a different setting of the ring. In such a case it is necessary to take out the valve disc and machine its lip A until the proper distance of this lip over the adjusting ring is obtained, after first determining the position of the adjusting ring for the desired blow-down. This procedure involves tedious trials.

Where gauges for finishing the valve disc and adjusting ring are furnished by the manufacturer of the valve, it is comparatively easy matter to machine these parts when making repairs. When the time comes, however, to overhaul the valve, it is generally found that all gauges are lost or unavailable. In order to eliminate the tedious machine work in overhauling and adjusting valves like those in Figs. 3 and 6, the modifications as shown in Fig. 7 were devised. The lip of the valve disc has

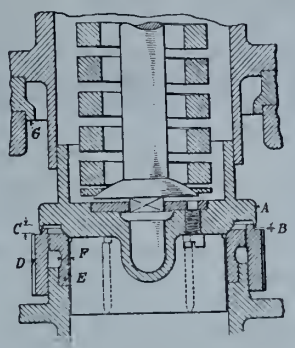

FIG. 6. MODIFIED SAFETY VALVE OF TYPE 3.

been cut away and the diameter of flange slightly reduced. The shape of the blow-down ring has been changed entirely, as shown, and made somewhat similar to the one in Fig. 4. The different action of the two rings D in Figs. 4 and 7 as regards popping has already been explained. The main feature in the ring of Fig. 7 determining the blow-down is the angle E. This angle, 36 deg., 30 min., has been found to give a range of blow-down of from 4 to 9 lbs. The laboratory tests on the popping and blow-down of this improved valve have given very good results.

Discharge Capacity

It is well known that when steam under pressure is allowed to flow through an opening, the maximum discharge will be obtained when the lower pressure is equal to or less than 58 per cent. of the higher pressure. When such conditions obtain, the pressure at the throat section, or most contracted part of the chan-

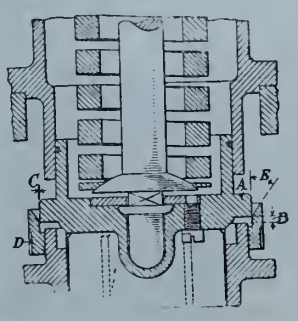

FIG. 7. ANOTHER MODIFIED VALVE OF TYPE 3.

nel through which the steam is flowing, will be 58 per cent. of the higher pressure, regardless of how much the pressure in the discharge chamber will fall below this value. The weight of steam discharged can then be calculated from Napier's formula: Flow in pounds per second = absolute pressure × area in square inches ÷ 70. If this is applied to the safety valves shown in Figs. 1 to 7, it will be found that the valves of Figs. 1, 2, 4, 5, and 7 undoubtedly will have their throat section at the inner circumference of the valve seat. Therefore, the area of opening at this section will determine the discharge capacity of the valve, provided the resistance to the flow is not made great enough to raise the pressure in the valve casing above 58 per cent. of the pressure under the valve seat. Making allowances for reductions of the free opening over the valve seat caused by guide wings, the following approximate formulæ, as given by some manufacturers, are obtained for calculating the discharge capacity:

$W = 149$ lpd for a flat seat

$W = 105$ lpd. for a 45-deg. seat

where W = discharge in pounds per hour
l = lift of valve in inches
p = absolute pressure under valve, lb. per sq. in.
d = diameter of valve seat in inches.

For equal lifts, then, the flat seat will give a greater discharge than the 45-deg. seat, which is obvious when it is considered how the 45-deg. seat restricts the throat section of the valve as compared to the flat seat. It should be mentioned here that the discharge capacity will be influenced to some extent by the smoothness of the approach to the throat section. On this account, the valve of Fig. 5 should give an exceptionally good discharge capacity, which seems to be borne out by the meagre test figures available. With valves of the shape shown in Figs. 3 and 6, it is frequently found that the actual discharge capacity will fall considerably below that obtained by the above calculations. This, no doubt, can be accounted for by the throttling of the discharge channel under the valve lips, especially at the lower lifts.

Repair and Adjustment

Bearing in mind that a safety valve, to be successful and satisfactory, must not have too delicate an adjustment nor require too frequent overhauling, it seems advisable to alter the valve in Fig. 3 to the type shown in Fig. 7, where repeated attempts at obtaining satisfactory operation of the old type have failed. Such alteration can be accomplished easily and cheaply, as the only new part to be made is the adjusting ring D, and the only part to be machined is the valve disk. The result will be an exceptionally rugged valve having no delicate parts, and one which can be easily overhauled and adjusted without expert assistance.

Grinding

For grinding a valve to its seat the most satisfactory grinding material is powdered glass and machine oil. It is easiest and most expedient to grind a valve cold, and this will in most cases produce entirely satisfactory results. Only where repeated efforts at making a valve tight by these methods have failed, should hot grinding be attempted. The hot grinding is a trying performance to any workman, and will only be an approximation to actual working conditions in any event, as a grinding at the actual temperature under which a safety

valve operates is out of the question. Where all other methods have failed to produce a tight valve, the design shown in Fig. 6 will sometimes serve. By inserting the raised seat E and taking care to machine this so that its weakest section F will be between the old valve seat and the new, there is an opportunity for this raised seat to adjust itself to the valve, regardless of what expansions and contractions may be taking place in the metal of the old valve seat. Frequently this will produce a tight valve. The construction shown in Fig. 6 is an improvement on the valve shown in Fig. 3, but the same, or a similar design, can be applied equally well to most other types. In making this alteration to a valve it is necessary to have a new valve seat E and adjusting ring D, and to insert a distance piece G under the valve bonnet in order to raise the bonnet the same amount the valve has been raised from its former seat. The author has seen this method applied frequently and with great success.

Another point, often misunderstood in repairing a safety valve, is the amount of clearance to give to the guide wings under the valve disk in the valve bore. No attempt at a very close fit of these parts should be made, as such would only increase the chances of the valve sticking. A suitable clearance for a 4½-in. valve bore is 1-32 in. on the diameter, or 1-64 in. on each side.

HEATING BY STEAM AT DIFFERENT PRESSURES

RECENTLY in Chicago tests were made to determine the relative cost of heating with steam at atmospheric pressure as against 3 to 5 lb. pressure in modern office-building plants. In an analysis of the problem a heat requirement of 5,000 B.t.u. per hour was taken. On the whole, it appears that there is no appreciable difference in cost in heating at different pressures. There is, however, an advantage in higher pressure from the standpoint of first cost of plant, because as the pressure is greater the plant may be smaller. This factor, however, has a limited value in practice unless excessive pressures are used. As a matter of fact, any plant designed to work at 5 lbs. should have margin enough to work perfectly at atmosphere, and vice versa, so that in the end the cost of heating will be identical in both cases.

Canadian Westinghouse Co. Elects Officers.—At the annual meeting of the Canadian Westinghouse Co., held at Hamilton on March 27, the following elected to the directorate of the concern: H. H. Westinghouse, Hon. Lieut.-Col. Paul J. Myler, L. A. Osborne, Thomas Ahearn, Sir John M. Gibson, K.C.M.G., John F. Miller, C. F. Sise, Warren Y. Soper, Charles A. Terry, Guy E. Tripp. The officers are: H. H. Westinghouse, chairman; Hon. Lieut.-Col. Paul J. Myler, president and treasurer; L. A. Osborne, vice-president; F. A. Merrick, vice-president and general manager; John H. Kerr, secretary; N. S. Braden, manager of sales.

ADVANTAGES OF ECONOMIZERS

BOILER plant efficiency can be considerably increased by adding economizers, which are used in most European plants, but find little favor in this country. The objections ordinarily offered are:—Their initial cost; reduction of available draft and, in many plants, necessity of installing mechanical-draft systems; cheap fuel (speaking comparatively); low load factors; complication of the power-plant outlay.

The chief reason that they are not used more generally is that their value is not realized. It is difficult to reason out just what effect load variations have upon an economizer as a heat absorber. If plants were operated continuously for 10 or 12 hours and completely shut down the rest of the time, the saving would be in proportion to the load factor, but where the load remains on, and only varies from overload to underload, the value is difficult to determine. Since however, such plants are ordinarily operated uneconomically at both high and low loads, and since economizers are of greater value the lower the boiler efficiency, they are particularly needed in plants having variable loads, and the saving in fuel, if not more, will be at least proportional to the load factor. Much depends upon properly proportioning the installation, and, therefore, before an economizer is decided upon, a plant must be closely studied and the governing factors, such as flue-gas temperature, feed-water tempperature, weight of air per pound of coal, load factor, character of load, etc., very closely predetermined.

UTILIZING EXHAUST STEAM

THE value of exhaust steam for heating and the consequent saving effected has been demonstrated, and many plants take advantage of it, but the practice should be more general. Even plants operating condensing could bleed the low-pressure receiver of a compound engine or the low-pressure stages of steam turbines and distribute this steam through the buildings. In power plants where economizers are not employed and the temperature of the water is low when fed into the boilers, this partly expanded steam could also be used to advantage in feed-water heaters.

In plants where large quantities of low-pressure steam are required and the pressure cannot be expansively reduced in a cylinder or turbine, a saving still could be made by generating this steam in a boiler under low pressure. It has been experimentally determined that there is about 6 per cent. difference in boiler efficiency between generating steam at near atmospheric pressure and at 350 degs. Fah., because of the increased temperature difference between the furnace gas and the boiler water, greater heat absorption and consequently lower flue-gas temperatures.

REDUCIBLE LOSSES IN POWER PLANTS

THE greatest and most neglected loss in the average boiler plant is from excess air. The magnitude of this loss at different CO_2 percentages is applicable to any fuel, liquid, solid, or gaseous, if its available hydrogen percentage is known. The impression prevails that coal must be burned with about 50 per cent. of excess air. Some authorities claim that going beyond 10 to 12 per cent CO_2 the loss due to incomplete combustion will offset the saving effected by reducing the excess air. This opinion is based upon certain types of installation only, and should not be accepted and disseminated as a general condition. Some few up-to-date plants are averaging 17 per cent. CO_2 with bituminous coal, without serious losses due to incomplete combustion.

One objection to high CO_2 is the extremely high furnace temperature and consequent rapid depreciation of furnace linings. For this reason many maintain 10 per cent. CO_2 as the maximum. With low percentages of excess air, proper design of combustion space becomes much more important to prevent incomplete combustion and too high furnace temperatures. Exceedingly high furnace temperatures have no real advantage and several disadvantages, therefore heating surface exposed directly to the fuel bed to reduce the furnace temperature will not only cause a decrease of the slagging effect upon the firebrick, and thus increase the CO_2 popssible to maintain, but will also increase the efficiency of the boiler due to the heat radiated directly to it, and will increase the boiler capacity without increasing the flue-gas temperature. With a proper furnace volume, smoke will not form if provisions for gas mixing are maintained and the temperature does not drop off too low or the boiler is not forced too much. Velocity of gas, time of contact, and hydraulic mean depth are important and deserve thorough study under all conditions of installation. Not much is being done in this direction and quite large boiler builders ignore the matter altogether.

Boilers can be operated at two times their rating, and more, but not economically unless designed for it; with the rates of heat absorption obtained at present in most installations, if operated at very high ratings the loss will be too great, unless the temperature of the escaping gases be reduced in economizers. The increase of velocity will cause draft loss, but this is not so serious, for the necessity of installing mechanical draft brings other advantages. With high ratings and high velocities the power required to produce the draft becomes of interest. Fear that so much of the steam generated will be required to produce the draft that the advantages obtained will be offset is unfounded, if the blower is designed for efficient work and driven by an efficient engine or motor.

Electricity and Hydraulics

OPEN CIRCUITS IN D. C. ARMATURES*

A VERY frequent form of breakdown to all direct-current armatures is that of an open circuit, which may be due to broken wires at a point close up to the commutator, and between that and the armature coils, or may be only due to a melted connection on the commutator lug. There are several causes for this defect, which may conveniently be classified as follows:—

(a)—Mechanical causes.

(b)—Electrical causes.

Considering first the mechanical side of the question, it will be found that in nearly all cases there is to some extent a slight movement between relative parts of the armature; that is to say, between the windings and commutator. Relative movement or vibration can be set up by a faulty drive or even by the rotation of the armature itself, if the machine is not securely fixed to or on a suitable foundation. Perhaps the most frequent cause of this class of breakdown is a loose key on either the commutator or the armature core, and in this connection the following example demonstrates a failure of this type.

The machine in question is of 60 horse power, and runs at a speed of 600 revolutions per minute on a 440-volt circuit. The laminated core of the armature windings is fitted direct on the shaft, and held in position by a key 13¼ ins. long by 1¼ ins. wide by ⅝ in. deep. The movement of the core on the key had apparently been taking place for some considerable time, and the wearing away of the key and also of the shaft was very considerable. Both the key and the shaft are now covered with circumferential grooves caused by the rubbing of the individual laminations of the armature core. The position of the ventilating ducts and also the alignment slot in the core remained normal. As a result of the breakdown, it was necessary to carry out the rebuilding and rewinding of the armature, including a new shaft.

Considering next the electrical causes of this type of breakdown, a machine that is run above its rated output is more liable to break down on account of the overheating of both the commutator and the conductors, which frequently reaches such a point that the solder in the commutator lugs is melted out. Also, as the commutator wears down, the current carrying capacity is thereby reduced, though at first not very appreciably. The time usually arrives, however, when the section of copper is so much reduced that overheating takes place, and the connections suffer. Machines have been known to break down repeatedly, due to melted connections caused by a commutator of restricted design, and after a new commutator of more ample proportions has been fitted, the same machine has run satisfactorily. Open circuits, broken wires, or bad joints very quickly show their presence, as the machine commences to spark violently each time the two ends of the open circuit come under the brushes, and if this is allowed to continue, the commutator is very soon burnt, and, as often occurs, requires several new sections of both copper and mica fitting.

*Article in Vulcan by a member of the staff.

CYCLE COUNTER OR TIMING DEVICE

AS IS generally known, it is not possible to obtain satisfactory results in the testing of time elements of high accuracy relays and of circuit breakers, with a stop watch, particularly where the selective action of the circuit breaker is essential. For this purpose, the Westinghouse Electric & Mfg. Co. of

CYCLE COUNTER OR TIMING DEVICE

East Pittsburgh, Pa., has developed the cycle counter illustrated, which is a device for indicating definitely the number of cycles required for the relay to close its contacts.

The mechanism of this timing device consists essentially of an electric self-winding clock, the escapement of which is operated by an alternating current oscillating magnet instead of a pendulum or balance wheel. At each cycle, one tooth of the escapement is released. The self winding clock periodically rewinds by means of power supplied from a shunt connection to the circuit when the cycle pointer has made 60 revolutions, the equivalent of 3,600 cycles. This arrangement keeps an even tension on the escapement, Thus, the escapement magnet is not depended on to drive the indicator, but simply to regulate its speed. The power for driving is furnished by the clock mechanism.

In operation the cycle counter is connected in series with the relay on a circuit adjusted to give the current value at which it is required to test the relay. When the circuit is closed, the "cycle" pointer begins to revolve, one step per cycle, and continues to do so until the contacts are closed. The instrument acts as though it had no inertia; that is, it starts the instant power is applied and stops the instant power closes.

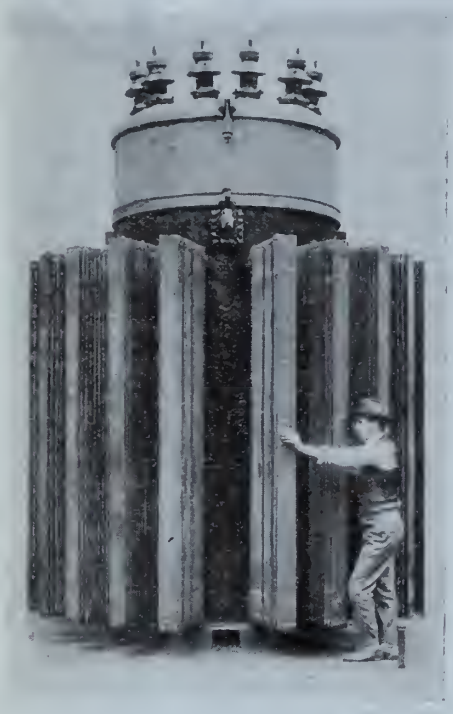
Although primarily designed for use in testing or adjusting time-element relays, this instrument is suitable for a great variety of testing. Its particular field of usefulness is for measuring elapsed time intervals of time too short to be satisfactorily observed with a stop watch and where readings in steps of one alternation are sufficiently accurate, obviating the use of complicated and expensive apparatus such as chronographs or oscillographs.

Given a known frequency the readings can be reduced to seconds if desired. Conversely, by connecting the instrument to a circuit for a definite period of time the frequency can be determined. By adding contacts to machine tools, elevator machinery, etc., the time required for various functions can be determined. It will also be found useful in many laboratories and test rooms for timing purposes.

GIGANTIC VOLTAGE REGULATOR

THE accompanying illustration shows what is claimed to be the largest piece of apparatus of its type which has ever been built. It is a self-controlled, induction feeder voltage regulator of the oil-insulated self-cooling type and was recently completed by the Westinghouse Electric & Mfg. Co., East Pittsburgh, Pa., for a large power Co., in the

Southern States. It is rated at 600 k v a., 3-phase, 60 cycles, 13,200 volts, with 10 and 20 per cent. regulation at 262 and 131 amperes, and is designed for operation out doors with full-automatic control self-contained. When installed, the regulator will be connected to the low voltage side of a 6,000 kva.



GIGANTIC VOLTAGE REGULATOR.

bank of 44,000 to 13,200 volt transformers on the power Co.'s line, and by its use the power from the line will be delivered to the consumer with the voltage maintained continuously at normal value.

KEROSENE AS A GAS ENGINE FUEL

By L. G. Heimpel, O.A.C.

THERE are hundreds of gasoline engines in use on Ontario farms at the present time, which are not the cheap source of power that they once were, and still should be, because of the recent rise in price of gasoline. A gasoline engine in good working order, and with gasoline at fifteen to twenty cents a gallon, is as satisfactory and as cheap a form of power as any other within the reach of the average farm.

Some years ago, gasoline was considered fairly good in quality when it tested 70-72 (Baume scale). At the present time it tests all the way from 59 to 66, which means that the speed with which it evaporates has decreased by the difference between these figures. In other words, volatility, which is the quality which makes it valuable as an internal combustion engine fuel, has deteriorated by that amount. The hydrometer (Baume scale), gives the test of average kerosene (coal oil), as from 42 to 46, which shows us that the difference between the volatility of coal oil and that of gasoline is growing less. In spite of the fact that the quality of gasoline is deteriorating we find the price rising—almost doubling that of a few years ago—and it behooves us to find some way of using a cheaper fuel for our gasoline engines.

Kerosene as a Substitute

For this purpose we have found kerosene, as well as naptha and fuel oil, to be quite satisfactory. Furthermore, it is an easy matter, as well as one that involves little expense, for any man who has taken the trouble to find out why and how his engine runs, to convert his engine, which was made to burn gasoline, into a kerosene burning engine.

The Relation of Kerosene and Gasoline

Before going on to describe the essentials of a coal oil burning device, we shall endeavor to show what gasoline and kerosene are, and how closely these products of the oil refinery are related. Both are products of petroleum. The crude petroleum is distilled in large iron stills and purified. The mass of oil is heated from 120 degs. C. to 150 degs. C. and held at, or near, the highest point mentioned, and all the vapor that passes off at that temperature is called gasoline. When no more vapor passes off, the temperature of the mass is raised from 150 degs. C. to 300 degs. C., and all vapor passing off at that temperature is condensed in a separate tank and forms such products as kerosene, naptha and fuel oils. Kerosene is therefore composed of the same constituents as gasoline, but it will not evaporate as readily as the latter, and it contains a larger percentage of carbon. Kerosene really contains more heat units per gallon than gasoline, but the problem before us is—how to get them out?

The conditions essential to the burning of kerosene are:—

1. Kerosene must be heated to its evaporating point outside of the cylinder and held at that point until it is ignited by the electric spark in the explosion chamber.

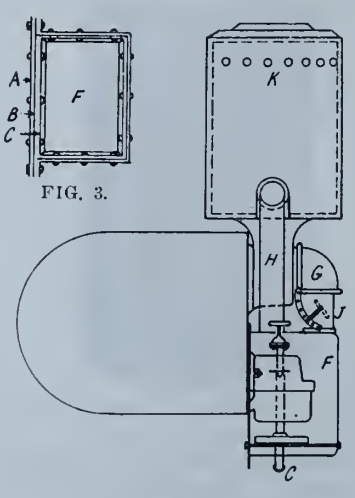


FIG. 3.

FIG. 1.

2. The air which is drawn in through the carbureter must be heated.

3. Water must be fed into the cylinder at the same time.

Heating the Oil

It is first of all necessary to state that up to the present we have discovered no satisfactory method of starting our engines on anything but gasoline, and hence appliances for this purpose must be provided. There are two kinds of fuel feeds in use at the present time—first, the gravity feed, in which the fuel tank is above the carbureter and the feed regulated by a float or diaphragm, and second, the constant level feed, in which we have the fuel level kept uniform by pumping a surplus of fuel into it; the excess running back to the tank through the overflow pipe.

The devices employed for heating the fuel in a gravity-feed engine are illustrated in Figs 1 and, 2 Fig. 1 representing an end view of a cylinder, carbureter and muffler of a gasoline engine, while Fig. 2 is a side view of the same. The dotted lines show the carbureter and heating tank D as they are enclosed in the box F.

On its way from the tank to the cylinder the oil passes through pipe A in the stand-pipe B, which is also a sediment and water trap, then through pipe C into heating tank D, from which it is drawn into the expansion chamber through the needle valve E. The heating tank should be either a thin rectangular tank holding from one-half to three-fourths of a pint of fuel, depending on the size of the engine, or it may consist of a coil of perhaps six or eight feet of ½ in. flexible copper tubing in which the oil is heated. In order to keep the fuel hot enough it is necessary to heat the carbureter as well as the oil; this is done by enclosing the carbureter in the sheet iron box F and piping about 40 or 50 per cent. of the exhaust of the engine into it, allowing it to escape through a hole in the opposite corner of the box. This is done by cutting a hole into the exhaust manifold and leading the exhaust through pipe G into the heating box. In Fig. 1, J shows a home-made butterfly valve by which the amount of heat entering the heating box can be diminished or increased at will. The construction of the heating box F is explained in Fig. 3, and with a little modification a similar device can be made to fit almost any engine. In Fig. 3, A is a stiff sheet iron plate which is held in place by being clamped in with the gasket on the studs which hold the carbureter. The top, bottom and one side of this box are one piece of metal bent to shape. The ends are of the same material and are fastened to the sides by bending the edges to form a flange, then bolting the sides and edges together with stove bolts. The joints can be made as tight as necessary by inserting a layer of asbestos paper.

Starting an Engine

The operation of starting an engine equipped in this manner is as follows:—

1. Close stop cock M so as to prevent kerosene from running into the carbureter.

2. Drain the kerosene out of the carbureter and heating tank through stop-cock N, after which close N.

3. Open stop-cock L to allow gasoline to run into carbureter and start the engine as usual. When it is hot, all that is necessary to change to kerosene is to close stop-cock L and opening M, so as to allow the kerosene free passage to the carbureter.

The principle for heating the fuel in an engine with a pump and constant level fuel feed remains the same, but

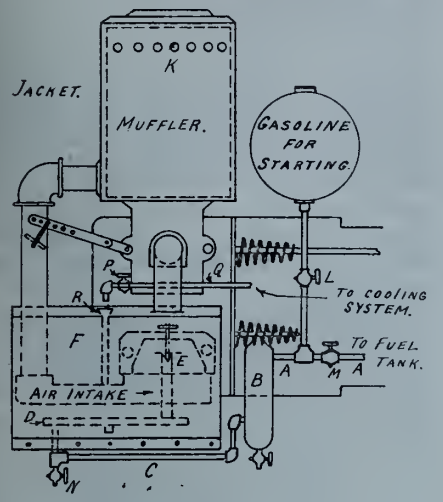

FIG. 2.

since a far larger amount of fuel is being pumped through the system than the engine requires, it follows that the tank heater is not efficient. Therefore, we must resort to such a device as is shown in Fig. 4. In this figure, O is the end of the cylinder of the engine; F is a coil of about 15 feet of quarter-inch pipe coiled around the exhaust pipe into which a series of holes have been drilled for the escape of hot gases; N is a sheet iron cover which encloses the coil of pipe.

The fuel is pumped through the pipe C, Fig. 4, into the carbureter at P, and the excess returns to the tank through overflow-pipe D. When kerosene is used the valve K is closed and the oil is forced through the coil F where it is

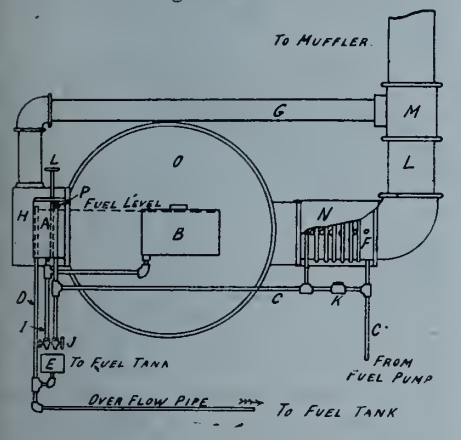

FIG. 4.

heated. When gasoline is used as fuel, opening of the valve K will allow the passage of the gasoline without heating it.

The heating of the carbureter is brought about in a manner similar to that in Figs. 1 and 2.

In starting an engine equipped as in Fig. 4, the following points are necessary:—

1. Drain kerosene out of carbureter through pet-cock on pipe I.

2. Fill tank B with gasoline. This tank should be large enough to hold for 20 minutes running. It is placed so that its top is level with the top of the carbureter and its bottom level with the bottom of the carbureter.

3. The pet-cock J is opened so as to allow the escape of all kerosene which is pumped through the pipe C, back to the tank.

4. Start the engine and when gasoline is run out turn on the kerosene by closing pet-cock J.

Heating the Air

It is necessary to heat the air so as to prevent condensation of the vaporized fuel particles into the liquid by the inrush of cold air into the air tanks. This is very important, and if the passage between the carbureter and the cylinder is a long one, and in a multicylinder engine it must be jacketed and heated with exhaust or the fuel mixture will condense on its way to the explosion chamber.

The best way to heat the air is to force the intake air to be drawn over the hot surface of the muffler or exhaust pipe. In Fig. 2 is shown a muffler with a jacket of sheet iron. The space between the jacket and the muffler should be no more than half an inch. All the air is drawn in through the holes K at the top of the muffler and is conducted through the pipe H to the carbureter.

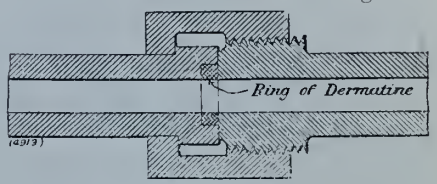
The Feeding of Water

Water is fed into the carbureter of a kerosene burning engine for two purposes, to prevent "knocking" and to prevent carbon deposits in the cylinder and consequent fouling of the ignition apparatus. Modern kerosene burning engines are fitted with a water carburter of similar design as the fuel carbureter, but when remodelling an engine not fitted for kerosene we find that a device such as is illustrated in Fig. 2 answers the purpose very well. Water taken from the cooling system of the engine passes through pipe Q and drops into the funnel R, thence into the air intake. The amount of water fed can be regulated by pet-cock P.

During the summer of 1916 we used a device as just described on the twenty horse-power engine driving the traction ditching machine used as a demonstrator by the Department of Physics of the Ontario Agricultural College. The writer made a number of actual working tests for the purpose of ascertaining the efficiency of kerosene and other cheap fuel oils as compared with that of gasoline. In each test we found that the gallon of kerosene did as much work as a gallon of gasoline. This means that with kerosene at from 12 to 13 cents a gallon and gasoline at from 33 to 35 cents, our fuel bill was cut to less than half of what it would have been had we been burning gasoline. Gasoline is high in price; the demand is growing; and the supply is limited; therefore we cannot see that it is likely to become any cheaper. For these reasons we hold that gas engine owners cannot do better than to equip their engines so as to burn kerosene.

HYDRAULIC JOINT PACKING

IN a recent issue of the *Philosophical Magazine* the Earl of Berkeley and Dr. Burton describe a simple form of joint packing, which is, they state, tight to start with and maintains this tightness



HYDRAULIC JOINT PACKING.

up to the highest pressures they have employed, and which have attained 1,500 atmospheres, or say, 10 tons per square inch. As will be noted from the accompanying sketch, the pipe ends are faced, and a recess is cut in one to take the ring of dermatine shown. Before assembly, this stands just a little over, and is thus slightly compressed when the joint is tightened up. Either red or black dermatine may be used, but the red, being harder, is more easily machined. The joint is said to be equally good for water or oil, and is as suitable for a flanged joint as for a screwed coupling. It is also said to be as satisfactory with large pipes as with small.

Cooling Electrical Machinery.—In the cooling of electrical machinery, with the high speed units of large output, the designer is seriously handicapped, says the *Electrician*. As turbo-alternators go in these days, the 15,000 kilovolt-ampere alternator is a machine of medium size. In such a machine the total loss is about 545 kilowatts, and an enormous volume of cooling air is required for carrying away the heat due to this loss. According to B. G. Lamme, a simple approximate rule for determining the quantity of cooling air required is that an expenditure of one kilowatt in one minute will raise the temperature of 100 cubic feet of air 18 deg. cent. Therefore, for a temperature rise of the outgoing air of 20 deg. Cent. above that of the incoming air, a loss of 545 kilowatts will necessitate a supply of ventilating air of approximately 50,000 cubic feet per minute.

Irrelevant Remark Defined.—She was a pretty girl, quite the belle of the class, and the cause of many a heart flutter. The teacher asked her one day if she could define an irrevelant remark.

"I can't just define it," she answered, "but I can give you an example."

"Well give us an example, please."

"Well, if I was going through a dark hall and met Billy Peterkins and he should ask me the time and I should say, "my your nose is cold," that would be an irrelevant remark.

Boiler-House Operation in South African Power Plants--I.

By T. G. Otley and Verney Pickles

In the January issue of the Journal of the South African Institution of Engineers, the subject of Boiler House Operation and Maintenance is discussed, with special reference to the Rand Power Co. plants. In what follows, both power plant superintendents and operators will find much to interest them, and no less so when cognizance is taken of the meantime steam coal situation not only in Canada, but in manufacturing countries the world over.

FOUR distinct power stations—Brakpan, Simmerpan, Rosherville and Vereeniging, are described by the authors, particular attention being given, however, to the boiler plant section of each, and in special manner to the coal and ash-handling equipment. Babcock & Wilcox water-tube boilers of a combined total of 102 units are installed.

Coal

The problem of burning coal efficiently is one largely dependent on the coal itself. It is a much simpler proposition with some coals than others, and although the results of experience given are chiefly concerned with Transvaal coal, the general principles outlined are generally applicable for burning coal on chain grate stokers. The great bulk of the coal burnt under our boilers is duff of a very small size, and a mixed coal of duff, peas, and small nuts. The most important factor of affecting efficiency is the different character, energy value, and size of the coal burnt. Few coals, even from adjacent pits, have the same character, even though the energy value may be approximately the same, and efficient results cannot be obtained unless the peculiarities of each coal be carefully considered.

Although there is a standard laid down by the Standards Committee for nuts, peas, and duff, yet each colliery manager appears to have his own ideas on the subject, and there is fortunately a tendency in many cases to increase the size of the screens above the ¼-in., defined as a duff screen mesh, but even though this may be increased to ⅜-in. or ½-in., the tendency is for duff coal—especially that from the Witbank district—to contain more and more absolute dust.

Table I. gives the results of screening tests on certain duff coals supplied to us under contract. The serious factor is that of the coal which passes through a ⅛-in. square mesh, a very large proportion is absolute dust, which either clogs up the fire or falls through between the links of the grate. At one time an attempt was made to burn one of the Witbank district duffs alone and dry as received, with the result that 70 per cent. by weight of the coal riddled through the grate into the ashpit unconsumed.

In order to burn duff coals efficiently, it is essential that they should be mixed with other coals, but the mixing has to be most carefully done. As far as possible separate outside bunkers are set apart for different coals, and, when different classes are to be mixed, care is taken that this is intimately done in the conveyor from the outside to the overhead bunker. The most serious consequence of the Brakpan bunkering arrangement is that coals cannot be mixed, and each coal—whatever its size and energy value—has to be burnt alone. It is general knowledge that duff coals burn better when wetted. A considerable difference of opinion exists as to the reason, but that it is possible to obtain higher furnace temperatures and a higher CO_2 is certain. Although there may be some chemical explanation, there is no doubt that some portion of the improvement is due to the moisture expanding and moving the particles of dust coal apart, thus allowing more even access of air through the fuel bed. Unless duff coal is wet it goes over the grate like a blanket and at a low furnace temperature, and if the draught is increased too high it breaks up the fuel bed into ridges, through which large volumes of excess and cold air enter the furnace, lowering its efficiency. Tests have shown that when burning dry duff alone, the CO_2 is only in the region of 6 per cent., whereas this can be brought up to 10.5 to 12 per cent. when evenly wetted.

Even though these results can be obtained when burning duff alone, it pays whenever possible to mix the duff with a larger mixed coal. We have found by experience that it pays to wet all our coals, whether mixed or duff, except only clean peas or nuts, of which, however, we obtain and burn a relatively small tonnage. In order to ensure success, the coal has to be wetted uniformly, and this is not such a simple matter as it might appear. If special provision were made in the original design of a station, it might be a much simpler matter, but, where the lay-out does not fit in, it is not easy to wet the coal evenly without making it too wet. Good results are obtained by spraying the coal as it falls from the filler into the conveyor buckets.

TABLE I.—SCREENING TEST ON DUFF COALS.

	A	B	C	D
	%	%	%	%
Through ⅛ in. square mesh	50.00	48.40	59.80	60.00
Over ⅛ in. and through ¼ in.	32.60	44.30	35.00	33.20
Over ¼ in. and through ⅜ in.	10.10	5.60	2.60	3.40
Over ⅜ in. and through ½ in.	5.00	.80	.40	1.60
Over ½ in. and through ⅝ in.	2.30	.90	2.20	1.20
	100.00	100.00	100.00	100.00

Sample A is designated a mixed coal of duff, peas, and nuts; the remaining samples are supplied as duff.

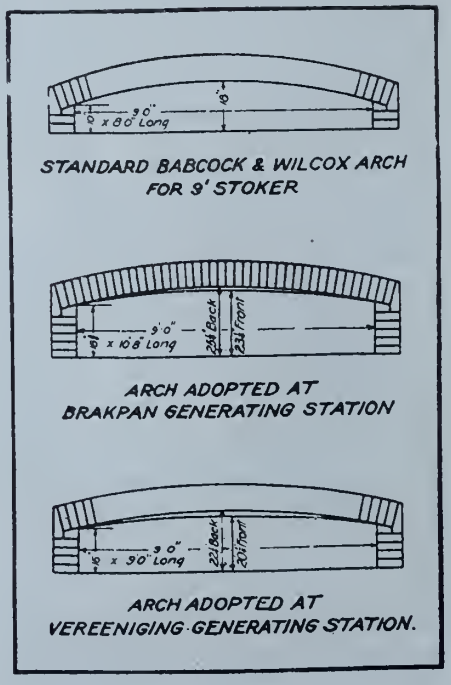


FIG. 1.

Objections to Wet Mixture

The most serious objections to this are that it vitiates the readings of the weighing machines to the extent of the added water, and a quantity of coal sticks to the buckets and is weighed over and over again. There is the further reason that if the coal is too wet it sticks in the overhead bunkers and in the chutes, and considerable labor is involved in getting it down to the stoker hoppers. The most successful scheme so far adopted has been to spray the coal as it leaves the overhead bunkers and enters the coal chute leading to the stoker hopper, but this can only be done when the feed is constant, that is, when the furnace conditions with regard to the thickness of fires and grate speed are not changed for long periods. If an alteration has to be made, then the coal is either too wet or too dry, and the results are unsatisfactory. The special difficulties of burning the low-value coals are further

dealt with when considering the boiler-house problems at Brakpan and Vereeniging.

Brakpan Power Station Boiler-house Conditions

The principal objection to the Brakpan bunkering arrangement previously referred to is that it does not permit of the mixing of the various coals burnt. In the old boiler-house, with a Witbank district mixed coal of duff, peas, and nuts is burnt, with average consumption about 1,300 tons per week. In the new boiler-house the coals burnt are obtained from the local collieries. These are of relatively low values—in one case of unusually low value, averaging something less than 2.20 kilowatts per pound (7,500 Btu. per pound), and containing between 32 per cent. and 36 per cent. of ash. If it were possible to evenly mix these coals with those of higher value, considerably better boiler-house efficiencies would be obtained. These low value mixed duff and pea coals have, unfortunately, to be burnt alone, and, as a result, the boiler-house efficiency is lower to-day than it was before the station was extended. The units sent out and the boiler-house efficiencies are given in Table II., and clearly show the drop that has taken place in 1915-1916 as a result of burning large tonnages of low value coal.

TABLE II.—BRAKPAN BOILER-HOUSE EFFICIENCIES.

	1914	1915	1916 (4 months)
Units sent out	36,324,000	116,725,000	42,185,000
*Boiler-house efficiency	76.2%	72.7%	71.2%

*Including pressure and temperature losses up to the turbine stop valve.

Although the efficiency is lower, we have gained considerably in economy. After all, the end we are striving for is not necessarily efficiency, but economy, i.e., the production of power at the lowest possible cost. We have no doubt whatever that, if a well-graded pea coal of an energy value of 3.45 kilowatts per pound were to be burnt at Brakpan, the boiler-house efficiency could be maintained, month in, month out, at 80 per cent., but this would be bought at too high a cost, i.e., at the expense of economy. It should be mentioned that the efficiencies given in Table II. are the average efficiencies over the years mentioned, and include all losses—pressure and temperature—up to the turbine stop valve, i.e., they represent the proportion of the heat energy of the coal available as steam energy at the turbine stop valve. With reference to the low value coal above referred to—2.25 kilowatts per pound—the proximate analysis of a good sample is given below:—

	Per Cent.
Moisture	5.6
Volatile matter	18.7
Fixed carbon	43.2
Ash	32.5
	100.0

This coal is so near the limit of what can be burnt commercially on chain grate stokers that a very slight variation downwards in value causes serious loss in boiler capacity and efficiency, and it is no infrequent occurrence to have to re-light the fires with higher value coal and reheat the arch before they can be got going again. It was only after an exhaustive investigation that the conditions necessary for burning those low value coals were reached. The principal factors are: Arch design; grading; draught; a thorough saturation of the duff or slack coal with water.

Dealing with the arch design first, we had the benefit of our experience at Vereeniging, where we had considerable difficulties in the early stages of the station in burning Vereeniging coal on chain grates. The arches now standardized for the conditions at Brakpan are shown in Fig. 1. These arches, although 9 ft. span, have only a rise of 4½ in. at front and 6½ in. at the back. It will be noted that they are 10 ft. 8 in. long, as against the standard arch of 8 ft. long. We find that they stand quite well when burning low value coal—furnace temperature of 1,200 to 1,300 deg. Cent.—but that with Witbank district coals and furnace temperature of 1,300 to 1,400 deg. they have a relatively short life, the last 3 ft. of the arch collapsing. The conditions giving the best results with the low value coals are:—

	Peas (½ in. to ⅞ in.)	Slack (0 in. to ¼ in.)
Fire thickness	6 in.	4¾ in. to 5' in.
Grate speed	No. 3	No. 4
Draught at uptake	1.2 in. to 1.3 in.	1.7 in. to 1.8 in.
Draught over fire	.50 in.	.50 in.
Coal burnt per square foot per hour	32 lb.	35.0 lb.

These conditions have to be maintained as steadily as possible. It is found practically impossible to do any regulating with these fires, and all variations of load have to be met by those boilers burning the higher value coal. The coal is now graded into two sizes, 0 in. to ½in. and ½ in. to ⅞ in., and as a result we are obtaining better efficiencies and higher evaporations per boiler. At the present time, the boiler-house efficiency is in the region of 72.5 per cent., and will probably come up to 74.5 per cent. We find it necessary to saturate the slack mixture (0 in. to ½ in.), but the peas (½ in. to ⅞ in.) can be burnt dry.

The colliery management find it difficult to maintain the energy value of the coal supplied at 2.25 kilowatts hours-pounds (7,700 B.t.u.), and it occasionally falls to as low as 1.82 kilowatts hours-pounds (6,250 B.t.u.). The principle trouble is to distinguish between the shale rock, and coal, as it passes over the picking belt, and it occasionally happens that the coal is thrown away and the rock and shale delivered to us. We are informed that where efforts have been made to burn low value slack coals in England it was found essential to thoroughly saturate the coal with water.

Grading the Fuel

The Vereeniging station was started up in September, 1912, and we were very soon in difficulties owing to the character of the coal. A further difficulty was that, as our whole requirements were obtained from one pit, the small by-product was insufficient for our requirements. A coal crusher was therefore installed. The combination of relatively low value—2.82 to 2.92 kilowatt-pounds (9,600 to 10,000 Btu. per pound)—and the large size and wide grading proved a very difficult problem, and one that engaged our attention for a considerable time. Although 17 or 18 boilers out of 20 installed were steamed, we could not obtain the normal full load electrical output for the station. The problem was first attacked by attempting to crush the coal to a smaller size. This improved matters. The coal from the crushers was then graded into two sizes, nuts (between 1½ in. to ⅞ in.) and slack (between 0 in. to ⅞ in.). In addition, we obtained a quantity of peas. Corneiia coal has the following average proximate analysis;—

	Per Cent.
Moisture	7.0
Volatile	22.0
Fixed carbon	52.5
Ash	18.5
	100.0

The grading of the coal certainly improved matters, but the solution of our difficulties was in the design of the stoker arch. It was found that with the standard type of arch the coal could not be got to ignite readily, with the result that the grates had to be run on Nos. 1 and 2 speeds. Under these conditions it was found impossible to obtain the normal evaporation from the boiler, and it was obvious, therefore, that as the coal was slow burning and difficult to ignite, that very much thicker fires would have to be run. With thick fires the fuel bed was much too close to the arch, with the result that the velocity of the gases was so great that they had not time to raise the brickwork to the high temperature which is necessary for continuous ignition. Experiments were made, and we ultimately adopted the type of arch shown in Fig. 1. The conditions which give us the best results with the large crushed coal are: 8 in. fires; No. 2 speed; 1.30 draught at the chimney uptake; and with the crushed slack:—4½ in. to 4¾ in. fires; Nos. 3 and 4 speed; 1.6 to 1.7 draught at the chimney uptake.

It is found that the high arch gives equally satisfactory results with the slack as with the large crushed, and we believe that even better results would be obtained were it possible to raise the arch higher still. We are, however, limited by the position of the mud-drum relative to the grate level. With the large crushed coal, when clean, we can steam

the boilers continuously at 25 per cent. overload, and still obtain a continuous efficiency of between 78 and 80 per cent. The efficiency when burning slack varies between about 66 per cent. and 75 per cent., depending upon the amount of dust in the coal. A peculiar characteristic of Cornelia coal is that, if it is left too long in stock on the outside coal staithes, it disintegrates badly. The effect of the duff on the burning efficiency of the crushed coal is also very marked, and we therefore endeavor to run with a minimum stock. The yearly outputs, station load factor, and boiler-house efficiencies, are shown in Table III.

A determined effort is being made to improve the average boiler-house efficiency, and there is no doubt that this will be effected if we can obtain a well-graded small nut coal, but having to take crushed run-of-mine coal, including slack and duff(which from time to time contains a large percentage of dust), renders this a very difficult problem, as the smaller nut made by the crusher the larger the percentage of duff and dust made.

TABLE III.—VEREENIGING POWER STATION OUTPUT, LOAD FACTOR, AND BOILER-HOUSE EFFICIENCY.

	1913	1914	1915	1916 (4 months)
U. S. O.	172,840,000	229,600,000	269,400,000	86,050,000
Load factor	56%	59%	67.4%	66.5%
*Boiler-house efficiency	69.8%	70%	72.1%	74.80%

*Including pressure and temperature losses up to the turbine stop valve.

Boiler-house Losses

We do not apply a CO_2 recorder to each boiler. In general there is one instrument to either two or four boilers, The CO_2 recorder is a good servant, but a bad master. A fireman, if left to himself, can readily obtain a good CO_2 chart, although the efficiency of the unit may be low and the boiler not doing its share of the load. This he can do by running a heavy fire at the back, thus allowing unburnt fuel to go over with the ashes, and by running on a reduced draught, thus reducing evaporation. These points, however, are very carefully watched, and as we aim at a CO_2 of 12½ per cent. there is little occasion for a fireman to specially nurse the particular boiler to which the recorder is connected. The gas sample is taken at the uptake between the economizer and the chimney, except in the case of those boilers with Green economizers, in which case the gas is taken from the uptake between the boiler and the economizer. The reason for this is that there is an unavoidable air leak with the latter type of economizer, which should not be debited against operation.

The average percentage of CO_2 is approximately the same at all stations, and is in the order of 10.5 per cent. when the boilers are steaming. The recorders are disconnected when the boilers are banked, as during this period the CO_2 would naturally be very high. The chimney uptake temperatures, however, vary according to the proportions of the boiler in relation to the grate area and the quantity of coal burnt. With the same CO_2, the boiler efficiency will naturally vary with the uptake temperature.

It has frequently been stated that it is possible to obtain the same efficiency with low as with high value coal. In commercial working this is impossible, even with the same CO_2 and uptake temperatures. For instance, when burning either Cornelia coal at Vereeniging, or Schapenrust coals at Brakpan, the chimney losses are never less than 14.5 per cent., whereas when burning Witbank district coals under exactly the same conditions of CO_2 and chimney temperature, the chimney losses are about 12.7 per cent. Furthermore, it is practically impossible to obtain the same furnace efficiency, as the unburnt carbon in the ash is considerably higher with low value coals containing a high ash percentage, and there is a further loss with those low value coals which require saturating with water, due to the evaporation of the added moisture.

The ashes are not regularly analyzed for unburnt carbon, but on frequent tests it has been found to be between 4 and 6 per cent. of the energy value of the coal. The larger the grade and the higher the ash percentage, the greater the loss due to unburnt carbon. It is usually considered that radiation losses from boiler and economizer casings are in the order of 2 to 3 per cent., but we believe them to be considerably higher than this, and more like 5 to 6 per cent. for our type of isolated boiler unit.

We estimate that the distribution of the coal energy at our power stations is as shown in Table IV. It will be seen that the chimney loss constitutes the largest of the three items making up the total loss. The greater part of this is inevitable, and is inherent in the design and proportion of the boiler and economizer. It is obvious that the gases cannot be cooled down to the temperature of the inlet feed water, unless the economizer heating surface is made infinitely large, but it would appear that money spent on larger economizers would have been a good investment. In commercial boiler practice the products of combustion are never discharged to the atmosphere at less than 100 deg. Cent., and consequently the steam goes away with the chimney gases to the atmosphere. In all our calculations we have taken the highest calorific value of the coal. It is difficult to defend this practice, as it is undoubtedly sounder and more logical to take the lower calorific value.

In comparing boiler efficiencies one should be careful to note whether the higher or lower value is taken, as it materially affects results. The loss with the ashes can to a certain extent be controlled, but it depends upon the character and size of the coal burnt, and is probably higher with us than in other power stations, owing to the fact that we burn coals containing a higher percentage of ash, and at Vereeniging too wide a grade to be burnt at the highest efficiency on chain grate stokers. The radiation loss is outside control, and is dependent upon the design of the plant. Boilers set in single units, exposed on all sides, must necessarily have a higher radiation loss than boilers in rows with brickwork settings. In order to arrive at losses due to banking, a series of tests were carried out at Rosherville, covering the whole cycle of operation. The tests lasted several days, the boiler being steamed off for a number of hours, then banked, and got away again in the ordinary way. It was found that about 1,800 lbs. of coal was consumed during the banked period, and including the coal used in bringing the boiler up to pressure and temperature. This was at the rate of about 175 lbs. per hour, or, say, 3 per cent. of normal load consumption. It is obvious that this is considerably less than the radiation loss when the boiler is steaming at normal load, as during the time that the boiler is on the bank the average gas temperature is very much less than when working.

Bonus Schemes

The matter of paying firemen and others a bonus to obtain higher efficiency has been given careful consideration, but no scheme has so far been evolved which would be fair to the men and to the company. Payment on CO_2 results is out of the question, as a high percentage can be obtained, and yet the boiler unity efficiency be low. Furthermore, it is more difficult to obtain a high CO_2 with some coals than with others. The usual bonus scheme is based on pounds of coal or B.t.u. per unit generated. Neither of these will be satisfactory under our conditions of working owing to the widely different values and characters of the coals burnt at the stations, and also owing to the circulating water inlet temperatures affecting the steam consumption of the turbines, both of which are outside the control of the operating staff. The coal consumption is largely affected by the load factor and the utility factor of the plant, and its condition of cleanliness, which is a matter for the maintenance department, and also outside the control of the operating employes. Taking all these factors into account, it is difficult to see how any equitable basis of payment can be arrived at, and we therefore rely upon intelligent supervision to obtain the results.

TABLE IV.—WEIGHTED AVERAGE BOILER-HOUSE EFFICIENCY AND LOSSES.

	Brakpan %	Rosherville %	Simmerpan %	Vereeniging %
Energy to water	71.2	74.6	76.1	74.8
Chimney losses	15.5	13.2	12.7	14.7
Loss in ashes	6.5	4.5	4.5	5.5
Radiation and banking	6.8	7.7	6.7	5.0
	100.0	100.0	100.0	100.0

REFRIGERATION DEPARTMENT

EXTRAVAGANT REFRIGERATING PLANTS*

By Victor J, Azbe.

ABOUT the most wasteful power plants are those of ice-making and refrigerating; many make three or less tons of ice per ton of coal, a few about six tons, and only the very exceptional plants reach the ten-ton mark. All except the very small ones and those near coal mines should be making ten tons of ice per ton of coal burned, and none less than six tons. One reason for the existing bad conditions is the low load factor. While during warm weather the equipment is forced far beyond its economical rating, in winter it stands idle. This low yearly load factor, which, in most plants, is between 20 and 40 per cent., is to a certain extent responsible for many plants not being more successful and profitable. There are ice plants, for example, the Polar Wave of St. Louis, that operate with a load factor of over 100 per cent. the year round. This is made possible by providing proper size ice-storage houses, which reduces the necessary size of power plants, machinery, ice tanks, etc., and consequently also the fixed and operating charges. Besides the variable load conditions, the following are factors responsible for uneconomic conditions:

Uneconomical Factors

Inefficiency in the boiler houses, where often the coal is burned with from two to four times the air actually required.

The fact that distilled water ice is made and uneconomical prime movers and auxiliary machinery are operated so that sufficient exhaust steam for distilled water will be obtained. This type of plant also condenses the exhaust steam in atmospheric condensers, with the result that the engines operate against a back pressure instead of under a vacuum.

Due to a lack of thorough understanding on the part of many operators of the physical laws governing the compression of gases, refrigeration is often obtained with from 20 to 40 per cent. more power than actually required. Many operators insist that ammonia compressors operate best with low back pressures, while exactly the opposite is true.

To be able to operate with high back pressures, ice tanks, brine tanks and coolers should be designed and piped so that proper temperatures will be maintained without too great a temperature difference between the air (or brine) and the evaporating ammonia. Where two (one high and one low) temperatures must be maintained, the power required per ton of refrigeration will be greatly reduced by installing high and low-pressure suction lines connecting with a multiple-effect compressor attachment, thus enabling the compressor to operate with very nearly the efficiency obtained with the higher back pressure.

A compressor operating against a condenser pressure of 185 lb. and with 12 lb. suction pressure, will require 3.07 b.h.p. per ton on ice-making, while the same compressor operating with 35 lb. suction pressure will require only 1.9 b.h.p., or a gain of 38 per cent. An economical ice plant will cool the liquid ammonia, leaving the condenser down to the temperature of the coolest water by passing the water on the way to the condenser through a liquid-ammonia cooler. The heat extracted here will be a clear gain. From the water cooler the ammonia will pass to a second cooler where the liquid ammonia will be further cooled by the evaporation of ammonia on the outside of the liquid coil at a high evaporating pressure, preferably 35 lb., or by gas returning from the expansion coils in heat exchangers. The distilled water, in the meantime, will be cooled to 40 deg. in the fore-cooler by liquid ammonia evaporating at 35 lb. pressure. Thus about 40 per cent. of the work will be done at 35 lb. and 60 per cent. at 12 lb. The ammonia gas from the liquid ammonia, water fore-coolers and ice tanks will then be led into two separate suction lines to either two different compressors, or to a compressor with the two ends separated and one compressing gas at 35 lb. and the other at 12 lb. suction pressure. By this arrangement about 15 per cent. less power will be consumed. and the capacity of the compressor and ice tanks will be greatly increased.

Raw-water-ice systems have been so perfected that ice can be made from raw water that is wholly equal to distilled water ice. Where the water is very bad, it can be purified or a multiple-effect distilled water system used, avoiding any occasion to employ uneconomical steam machinery to get the required quantity of ice water.

Compression System Improvement

The compression system of ice-making with simple non-condensing Corliss engines and its production of six tons of ice for every ton of 12.000 B.t.u. coal burned under its best conditions, high load factor and excellent operation, could be improved upon by various other combinations, as follows:

	Tons of ice per ton of coal
Compression, simple Corliss, non-condensing	6
Compression, compound Corliss, non-condensing	7
Compression, simple Corliss, exhausting into generator of absorption machine	8.5
Compression, compound Corliss, condensing	9.5
Compression, compound Corliss, exhausting into generator of absorption machine	11.

These estimates are for well-operated ice plants, and the production could be further increased by adding special devices and by special arrangements, economizers, multiple-effect compressor attachments, flooded and jet ammonia condensers, vertical small clearance compressors, heat exchangers, flooded systems, etc., also by using Uniflow engines supplied with highly superheated steam. In some refrigerating plants Diesel and semi-Diesel engines are used to drive ammonia compressors with great success, while in others they are not profitable, but this is chiefly the fault of improper design, management and operation and not of the oil engine.

By operating ammonia compressors properly, that is, with a high discharge temperature and leading the gas through a feed-water preheater, considerable heat could be saved, and thus allow, if economizers are not used, employing more efficient auxiliaries or discharging their steam into the generator of the absorption machine.

Condenser Efficiency

Condenser efficiency is also very important in ice and refrigerating plant operation, and it is regrettable with what persistence the low efficiency straight-pipe condensers are used, while there are excellent types of flooded, jet and other condensers on the market. Some of these condensers are from two to three times as efficient as those in general use, because they transfer heat from liquid to liquid instead of from liquid to gas. An entirely new type of condenser, employing high velocity and counter-current effect, gives a very high efficiency and remarkable results.

Many large plants are operated non-condensing, and while the exhaust steam, in winter, is used for heating, in summer, a large part of it is ordinarily wasted. It would pay some one to buy this steam and use it in an absorption ice machine. Another good combination would be an exhaust-steam absorption ice plant and an electric-light plant, with

*From a paper read before the American Society of Mechanical Engineers, New York City.

the resulting high efficiency of the two combined.

Opportunities for economy in ice plants are great, not only by better equipment and arrangement, but also by better operation, for many plants are ridiculously inefficient. While operating engineers are coming to realize the importance of frequently indicating the steam engine, they are slow in becoming impressed with the importance of indicating the ammonia compressor. Although simply inspecting the ammonia-compressor indicator card will not reveal much, by drawing the adiabatic and isothermal curve, and by drawing the suction and discharge pressures existing in the pipes leading to and from the compressor and noting their relation to the suction and discharge pressures in the cylinder, a good idea of conditions will be gained. Thermometers in the suction and discharge pipes at the compressor and proper interpretation of the readings obtained are also of great value in the efficient operation of an ammonia compressor.

The author knows of ice plants where compressors operate with only about 70 per cent. of their volumetric efficiency and, in addition, the wire-drawing of ammonia gas through improperly designed suction piping and suction valves causes an increase of 10 to 15 per cent. in the power required per ton of refrigeration, because the ammonia in the cylinder before compression is more rarefied than in the evaporating coils. These conditions would not have been discovered without the indicator.

REFRIGERATOR INSULATION*

By Robert F. Massa.

IN the following notes on refrigerator insulation, it is the writer's intention to call attention to several elementary physical facts—facts which everyone knows and the regard for which would seem to be engineering common-sense, and yet facts which are very apt to be neglected in insulating cold storage compartments. Some repair work recently done on refrigerators in a large New York hotel offers an excellent example of how not to insulate a cold room. The fact that this was a stationary installation does not affect its importance as an example of wrong method. These refrigerators, when originally built, were constructed by cementing cork sheets against concrete floor, walls and ceilings, with wooden strips set in the cork. The cork was applied in two layers, 2 inches thick each, the second layer being secured to the first by cement and the strips of wood being set in the last layer applied. To these wooden strips there was secured an inner lining for the refrigerator made of white porcelain-enamelled sheets of steel.

Case of Water-Soaked Insulation

Upon examining this refrigerator after several years' service, it was found that the insulation, particularly in the lower part of the box, was water-soaked, that the steel had been almost completely rusted out, that the wooden strips holding the metal in place had rotted away, and that the moisture had worked down through the floor and was getting into the wine room located directly below the refrigerator. The defect in this design lies in the fact that it is not possible to fit these enamelled sheets close enough to the cork to do away with air pockets, and, if these pockets exist, the variations of temperature to which they are inevitably subjected mean alteration of pressure within them, and, consequently, interchange of air with the outside, the deposit of moisture and its gradual accumulation.

Moisture Deposit Increase

The deposit of moisture is increased where the cooling surfaces are placed close to the walls of the refrigerator, this action being due to the greater deposit of moisture at the lower temperature, and further, to the greater variations in temperature to which air pockets near the cooling surfaces are subjected. This same difficulty of making a perfectly tight wall holds, not only with the white porcelain-enamelled sheets, but with all metal sheets and with glass refrigerator lining. These glass linings are one of the most attractive appearing linings for refrigerators, but for the above-mentioned reason are not desirable as ordinarily installed.

The method used for correcting this set of refrigerators consisted in removing all ofthe defective insulation, replacing it with pure cork sheets set in Portland cement, using two layers of 2-inch sheets as before, and then finishing the inside of the refrigerators with cement with rounded or cove corners. In this way all air spaces are absolutely eliminated and a practically permanent structure is secured. There is, of course, a tendency which cannot be avoided for the cement to crack as it dries. This is taken care of by scoring the surface in rectangles so that the cracking occurs on these lines, and after the cement has thoroughly dried these cracks are filled with a paint, *i.e.*, a white enamel paint that is used for a final finish on the surface. A refrigerator finished in this way is not as attractive in appearance as the glass, or, for that matter, even the porcelain enamel on metal, but it is certainly a more sanitary structure. Another way to overcome the cracking difficulty in the cement is to give the cork a skim coat of cement, bed into this either a sheet of expanded metal or wire mesh of some kind, and then apply a final coat of cement. The two layers of cement are used to avoid any possibility of air spaces being left if the metal is secured direct to the cork, and then only a final coat of cement applied.

A further difficulty in the original design of the refrigerators under discussion was brought very forcibly to the attention of the men who did the actual repair work on this job. The work, unfortunately, had to be done while the kitchens were in service, and, although the weather was not specially warm, the men found the interior of the refrigerators so hot that it was impossible to work any length of time without going outside to cool off. Ranges and steam kettles were so close to the refrigerators that there was only space sufficient for the men working on the ranges or kettles to get about them and for a rather narow passage behind them, *i.e.*, between them and the refrigerators. When one stops for a moment to consider the purpose of insulation, namely, to prevent the flow of heat into the refrigerator, it would seem reasonable to so arrange the building as to reduce as far as possible the temperature to which the outside of the refrigerator is subjected.

The insulating material—namely, pure sheet cork—is cemented with a special cement directly to the steel surfaces forming the compartment. The second course of cork is set in asphalt after the first course has been carefully pointed up with an asphaltic cement mixed with fine regranulated cork. In this way all possibility of air spaces is eliminated and the chance of any moisture accumulating is avoided. The inside surface may, in this case as in the insulation described before, be finished in cement, although in some classes of work the cement can be omitted and an asphalt finish used instead. One cannot conclude from the suggestion that cork can be cemented directly on to the steel in the construction of refrigerator compartments on board ship that a similar construction is suitable for ice-tank work in stationary plants. In this work the surfaces of the tanks are, in general, not particularly true. There is also the difficulty of rivet heads which must have the cork fitted about them. In work of this size this fitting is apt to be done carelessly, with the result that air spaces will occur and the cork be forced out of place by freezing and melting of moisture.

Difficulty has been encountered, in one or two installations which the writer has seen, with the use of cork that had not been sufficiently pressed previous to baking. This cork was not as dense as it should have been and had not the mechanical strength it should have had. More or less air spaces were left in the cork, into which there was, of course, the tendency for moisture to penetrate, and, where the temperature was very low, this moisture froze and pried the sheets apart, completely disintegrating the insulation and requiring that the entire work be done over again.

*From a paper read at the 24th general meeting of the Society of Naval Architects and Marine Engineers, New York City.

London, No. 3, C.A.S.E.—On March 9, the stationary engineers of London, Ont., held an open meeting in the C.A.S.E. Hall, Messrs. McGhie, Moseley and Corrigan of the Province of Ontario Stationary Engineers Examining Board were present and took part in the discussion. Of local men, Messrs. Mellon, Campbell, Moll, Lyons, and Fowler, were the more prominent spokesmen. Visiting engineers and the "Examining Board" were afterwards tendered a banquet at the City Hotel .

POST-WAR PROBLEMS OF LABOR

THE introduction of shell manufacture into Canada, created a new phase of enterprise which, up until three years ago, had practically been an unknown factor in this country's industrial activities. The rapid expansion of munitions making, coupled with the drain upon the man power of the land, had the effect of causing a temporary dearth of skilled mechanics in many lines of manufacture. This feature of an unprecedented situation threatened the success of an obligation suddenly undertaken by Canada's captains of industry. During the early period of the war, when the call for volunteers was meeting with a wonderful response, our factories were being depleted of the trained men upon whom much reliance had been placed for the achievement of the new task; that of producing munitions for the Imperial Government.

Our metal-working firms had never before been called upon to produce on such an extensive scale, besides, little time was permitted to form a plan of action to meet the need. Equipment was apparently the essential factor, and a feverish start was made to obtain the machines most suitable for the purpose. Guided by previous practice in other lines of engineering output, the tools ordered for the new venture were naturally of standard pattern, with few or any of the auxiliary parts eliminated. The urgency and magnitude of the demand for these tools, and the inability of the machine tool builders to deliver equipment, created an unprecedented situation, the result of which has been the means of revolutionizing, not only the shell making industry, but is likely to establish a new standard in future engineering practice.

Probably never before in Canada's history have the resources of plant and individual been more rapidly developed than during the past three years. Instead of the delay in the delivery of equipment proving a drawback, it has probably been a blessing in disguise. Had sufficient standard tools been readily available at the commencement of the shell game, there is a large possibility that the increased production would not have been as rapid as the changed conditions have proved it to be. Unable to secure standard tools, shell makers began to equip existing machinery with special attachments or devices for the accomplishment of certain operations. Scrap heaps were explored and machines that had been "dead" for years were pressed into service, with such remarkable success that a foundation was started upon which a new and highly efficient line of special single purpose machinery was designed and constructed.

Owing to the methods of manufacture, and the development of single purpose tools for specific operations, the problem of unskilled labor has not been as complex as it might otherwise have been, experience proving that men, and also women, who had no previous knowledge of machine shop practice, have been equally capable with skilled mechanics in the operation of special machines. The question, however, is: What effect will this have on post-war manufacturing conditions? The knowledge acquired in the operation of machinery by the majority of those now working on munitions, will, when the "game" is over, be a factor that must be included in the problem of future readjustment. It must be conceded that large numbers of present shell workers will class themselves as, at least, operators when the war is over, and normal conditions again prevail. The lengthy duration of the war, and the mechanical experience they have gained, both in the operation of machines and the accurate manipulation of tools and gauges, may well fit many of them for a place in future mechanical activities.

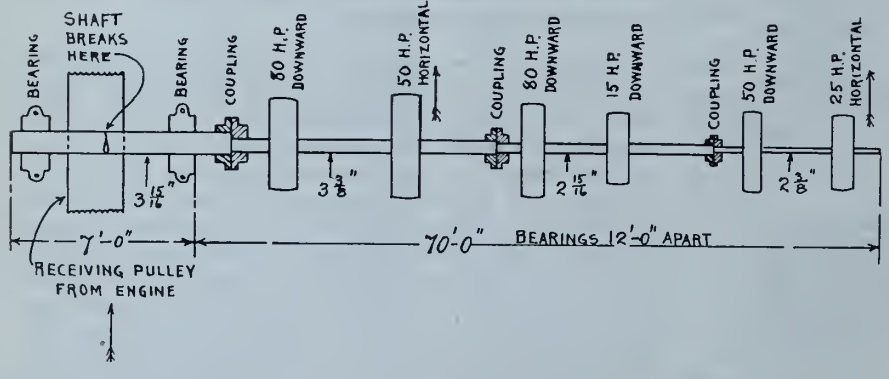
The Operators' Point of View

OVERCOMING TROUBLE WITH STEAM PIPE

By H. Westwood.

UNDER this heading in the January issue of the POWER HOUSE, there was an article by J. James, and also a sketch as to how he remedied the trouble. He states that after the load reached 280 amps. on each engine, they would start to race. Farther on in his article he states that when the steam gauge was attached to the pipe leading to one of the engines it was found they were not getting enough steam. If the engines raced it was steam pressure behind the piston that made them do so and the fact that he put a receiver 8 ft. x 12 ft. on the main steam line leading to the engines only acted as a gas bag or storage tank between the engines and boiler, and the engines do not get any more steam than they did before the change.

If the two engines in question could not get enough steam through a 5 in. pipe before the change, they will not get any more now. Assuming that the boiler pressure was 100 lbs. absolute, the receiver would hold approximately 7.3 lbs. of steam; now, if the engines were not getting enough steam before the change, they have only to use a little more than what is being supplied by the 5 in. pipe per minute and he would be up against the same conditions as far as the flow of steam through the 5 in. pipe is concerned, but his trouble regarding the see-sawing of the engines would be eliminated.



LAYOUT OF SHAFT WHICH GIVES TROUBLE THROUGH BREAKING.

It is just like running a gas engine plant from pressure producers, with a holder between the engines and producers. If the engines are using more gas than the producers are supplying to the holder, it will, in the course of a short while, become empty, and the engines would be sucking the gas from the producer, likewise the engines referred to by Mr. James would be wire drawing the steam.

A Similar Case

I had a case something similar to the one referred to, two high speed engines direct connected to 75 k.w. d.c. machines. The boiler pressure was 150 lbs. gauge and these engines were designed to operate on 90-lbs., so we had a reducing valve in the steam line. When the shop load had dropped off in the early evening, and I wished to put off the 400 k.w. generator and change on to the two high speed engines, there was difficulty in getting them on the board, I would start them up, adjust the voltage, and connect them to the board. They would operate in parallel with the large unit O.K., but as soon as I kicked the breaker on the large unit, one would try and pull all the load and out would go the breaker and likewise the second, because the load was too much for one. So I would put the large one on the board again till later in the evening when the load would be still lighter; then things would go all right.

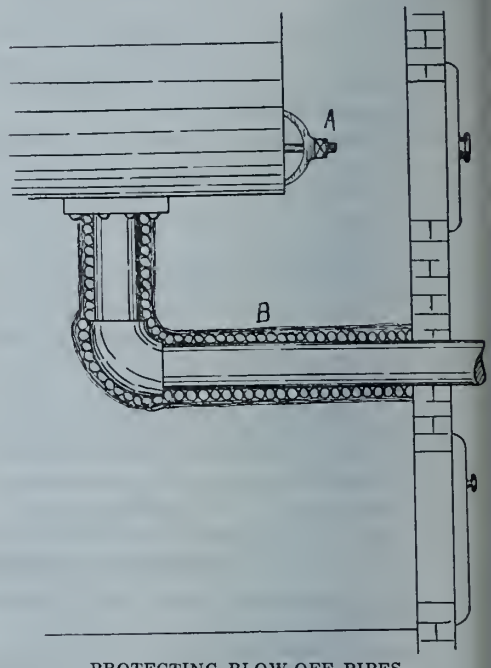
But one holiday there was not sufficient load to warrant putting on the larger unit and I left the two small ones to do the job. Whenever a load something near the rating of the machines hit them, they would see-saw and throw the breakers.

Indicating, these two engines showed that the steam was wire-drawn and a gauge attached to the steam pipe showed a drop in pressure, but a few turns on the nuts on the end of the spring of the reducing valve remedied the trouble.

PROTECTING BLOW-OFF PIPES

By J. E. Noble

CAST iron sleeves and file brick covers for protecting blow-off pipes are expensive and often bothersome, as they will persist in cracking and falling off at the



PROTECTING BLOW-OFF PIPES.

wrong time. A simple, inexpensive, and efficient covering, can be made as follows:—Cover the blow-off pipe from the boiler shell to the back wall with ⅜ in. asbestos rope, as shown at B. Make a mixture of two parts asbestos cement to one part fire clay and enough water to make it into a working plaster. Cover the asbestos rope with a coating of this mixture and the job is done. It is a good idea to cover hand hole bridges as at A, with a fire clay and asbestos mixture. If this is done the hand hole bolts will last for many months and the bridge for years.

TROUBLE WITH SHAFT BREAKING

By E. J.

A CORRESPONDENT submits the following account of trouble through breakage of a shaft. We have a line shaft about 70 ft. long, which delivers a total horse-power of approximately 300, taken off the various pulleys in the directions shown in sketch. The shaft is driven by ropes received by a pulley on a 7ft. length of 3 15-16 in. shaft. The other shafts are respectively 3⅜ in. x 30 ft., 2 15-16 in. x 25 ft. and 2⅜ in. x

15 ft., the bearings being about 12 ft. apart. The rope drive is from a corliss engine and revolves the shaft at 290 revs. per min. Considerable trouble has been experienced through the 3 15-16 in. shaft breaking in the centre of the pulley hub, and has been repeatedly checked up for alignment without any defect therein. Any suggestions by readers would be appreciated.

SHAFT TROUBLES

By John Ellethorn.

WHEN ammetic and voltmeter readings are taken on a line shaft and a heavy friction load is shown, it is usually stated by the investigator that the shaft is out of line and not leveled. In a recent test, in a laundry plant, where the friction load registered 45 per cent. of full load, the expert stated that the shaft was out of line. The shaft was re-lined, and bearings repaired, at considerable cost in time and money. New readings were taken, but the friction load had increased to 52 per cent. of full load.

The engineer, who was just an ordinary fairly intelligent sample of the profession, directed the attention of the investigator to the fact that the pull of the countershaft belts was practically all at one side of the line shaft, and that the belts from the countershafts to the machines was perfectly vertical, which meant a very tight belt.

In re-lining the shaft the cross belts, which were very short in some cases, and therefore had a high belt tension, had their tension increased, which would account for the extra seven per cent. All the cross belts were removed from the line shaft and a test showed a friction load of 5 per cent. only, a decrease of 35 per cent. from the first readings.

In many cases when a belt begins to slip, the man in charge will cut out a piece of the belt, thus tightening it up and incidentally increasing the friction and stretching the life out of the belt. The intelligent use of a good belt dressing would often save considerable work and prolong the life of the belt for many months.

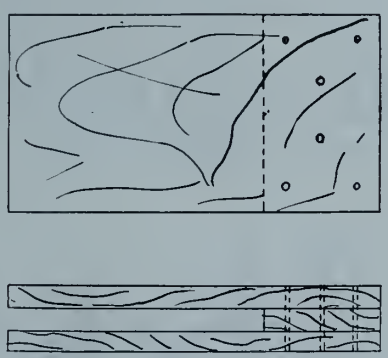
Many instruments are made to simplify the re-lining of shafts. Some are ingenious and useless and some are good if used intelligently and under proper conditions. If it is possible to have the power cut off from the shaft for a sufficient time to do the work, nothing can beat the lines, levels, plumb-bob, rule, and "gumption." I have seen men endeavoring to line a shaft while another shaft a few yards away and machines by the dozen were in full swing, causing such a vibration that no matter how tight the line was drawn, it would vibrate, while the "bubble" in the level would proceed to do a "tango" every time it was placed upon a hanger or bearing, and it was impossible to keep the plumb-bob from swinging. The use of one of the patented devices was no better. Therefore, do your line shaft lining when there is a shut down, Sunday, if no other day is available. If you shy at Sunday work, do it at night and sleep during the day. Of course, in some solidly built buildings the vibrations from one shaft to another would be next to nothing, but these later remarks refer to the other kind.

Make sure the fault is rightly located if the friction load is big. See that the hangers are not set too far apart for the diameter of the shaft and the load carried, that the diameter of the shaft is great enough to stand the pull at full load without springing, that the pull on the shaft, at the pulleys, is as close to the hangers as possible, that the pull is not all at one side of the line shaft, that as few belts as possible are vertical, and that the use of a good oil or grease is not forgotten.

PROTECTING BELT LACES FROM VERMIN

By J. E. McCormack

LAST summer the plant where the writer is employed was troubled with vermin which ate the leather lacing out of the rubber belts when machines were occasionally idle for a few days; even belts in regular use would sometimes have their lacing eaten during nights and Sundays. While experimenting



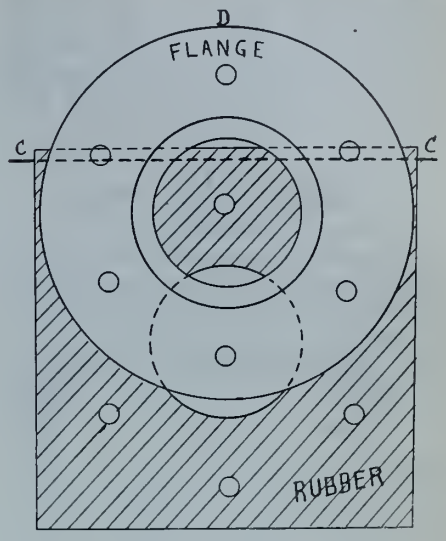
PROTECTING BELT LACES FROM VERMIN.

with various types of metal lacings to find one suitable for use on all of the belts, we protected the remaining leather lacings, when at rest, by placing over them shields made as per sketch, the dimensions varying with the size of the belt. The shields were made of 3 pieces of 1 in. board, nailed together and provided with a hole for a cord which was tied to the guard rail to prevent the shield from being carried to either pulley in case the belt was started up before the shield had been properly removed.

RENEWING GASKETS IN LARGE FLANGES

By John Port

MANY suggestions have been given for replacing rubber gaskets in large flangers, say 6 ins. and over, and a method I have used with success is shown in accompanying sketch. The bolts are removed and a steel wedge driven in at D, just far enough to get scraper in to clean the flange faces. A square of 1-16 in. sheet rubber, the diameter of the flange, is cut and the center hole and bolt holes cut out, and a piece of No. 14 soft copper wire is threaded along the top of the rubber, as at C C. The washer can now be drawn up from the bottom, or side opposite the wedge, without the washer



RENEWING GASKETS IN LARGE FLANGES.

falling down either on a vertical or horizontal pipe.

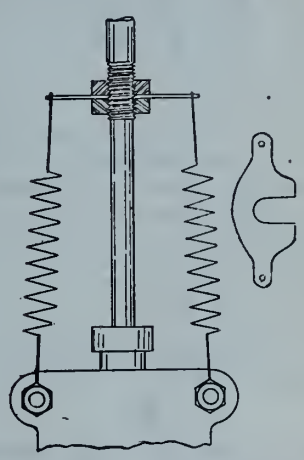
By using a soft wire, it is possible to keep the washer nearly flat; if a stiff wire is used the end of the washer would be heavily wrinkled. When the washer is in place the square ends are cut away. Some engineers advocate using a ring of rubber inside the bolt holes only thus saving considerable rubber. The idea is alright if care is used in tightening up the bolts, but it is easier on the flanges where a full sized gasket is used.

The wire can easily be removed from the flange washer by taking hold of it at C and holding the gasket at C. All that is needed is a gentle pull.

CURING AUXILIARY VALVE STEM TROUBLE

By W. D. B.

WHEN the auxiliary valve stem of a pump does not go through both ends of



CURING AUXILIARY VALVE STEM TROUBLE.

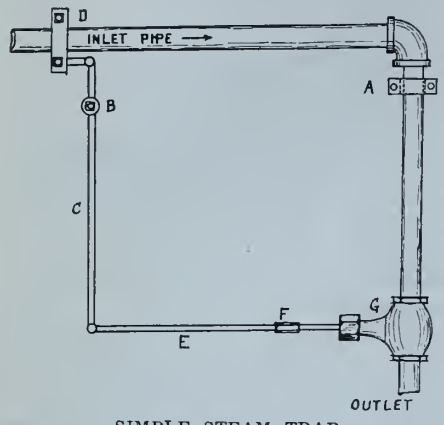
the steam chest the pressure on the inside end sometimes forces it out causing a short stroke. The writer found that an efficient method of overcoming this

was to cut a piece of sheet metal to shape A in sketch, which is then placed between the two nuts on valve stem nearest the steam chest. Springs are then connected as shown from the ends of A to any convenient parts such as the nuts on chest. Springs from old window blinds are quite suitable and are easily adjusted to balance steam pressure on inside end of valve stem.

SIMPLE STEAM TRAP

By L. U. N.

THE device shown in the accompanying sketch was devised by the writer for the purpose of performing the duties of



SIMPLE STEAM TRAP.

a steam trap, and gave excellent service during the period it was in use.

The inlet pipe is turned downward at elbow A and securely fastened to wall so that expansion in the pipe takes place in the opposite direction. At a distance of about 4 ft. along the inlet pipe, a bolt B is firmly fastened in the wall for the purpose of providing a hinge on which the lever C can oscillate. A collar D is clamped tightly on the inlet pipe and connected by a link to the upper end of lever C. The lower end of lever D is coupled up by rod E and right and left hand coupling F to spindle of globe valve G, the threads on the valve spindle having been carefully filed off so that it is free to move when operated by rod E.

In setting up the trap, the coupling F is adjusted so that valve G is open when cold, and after steam is turned on the increased temperature of the inlet pipe will cause it to expand away from A so that lever C closes the valve. The difference in temperature between the drain water and live steam can be carefully adjusted for when hot to suit the particular pressure in use, so that the presence of drip in the pipe will cool it sufficiently to contract its length and open valve G.

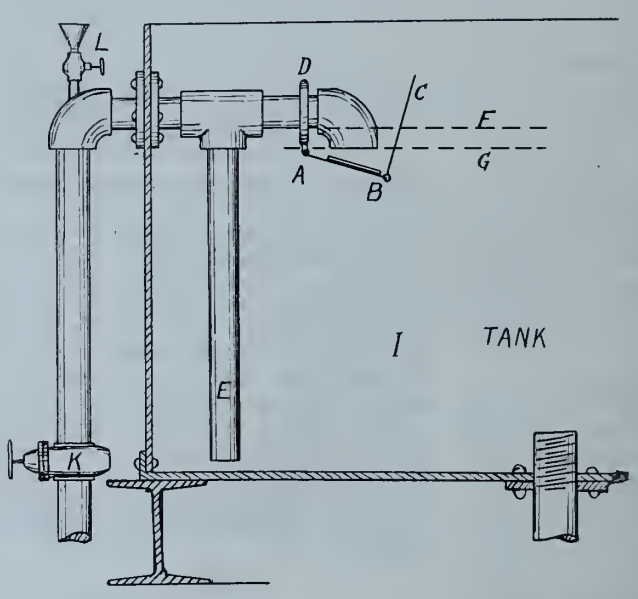
TANK SKIMMING AND EMPTYING DEVICE

By John Ellethorn

A LARGE water tank could only be emptied by allowing the water to run out through the pipe H. This pipe supplied a number of fixtures, and every time the tank was emptied sediment and other foreign matter would get into the taps causing considerable annoyance and work to get them into good working condition again. To overcome the trouble the pipe shown was connected to the regular overflow.

The end of pipe E reached to within one inch of the bottom of the tank. A strap D, was made to go around the pipe near the elbow, to this strap was fastened a disc of heavy galvanized sheet iron with a facing of leather or rubber in the center. The joint at A is made to be quite stiff, and the handle C is a piece of wire.

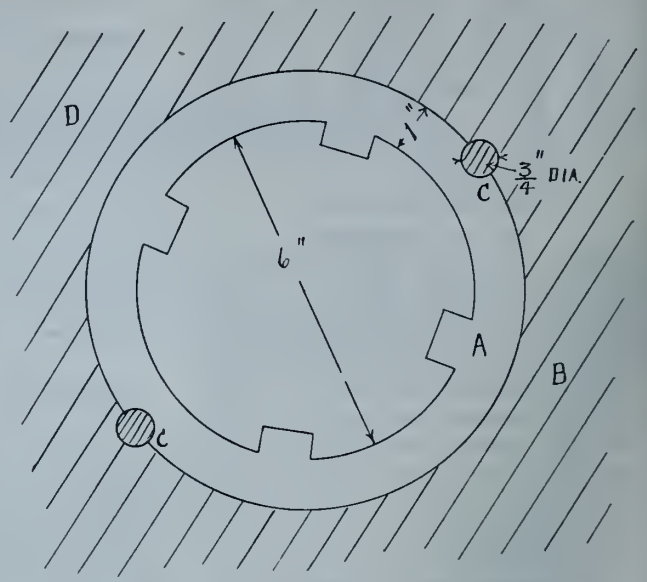
Much of the water in the tank came from the roof, bringing with it, leaves etc. These leaves would go from the tank through the overflow elbow, at the same time, part of the dirt at bottom of the tank would be drawn up through the pipe E. When the tank was receiving a large quantity of water, it would fill up to the level F, and then start to syphon until the water reached the level G, when the syphon would break.



TANK SKIMMING AND EMPTYING DEVICE.

When the tank required cleaning, a time was usually chosen when the tank was nearly empty so that water would not be wasted. The handle C was pulled up forcing the leather disc against the opening of the elbow. Valve K was closed and the pipe above it was filled with water through the valve L. Valve L was then closed and valve K opened quickly. This would start the syphon, men would get into the tank quickly, sweeping and stirring up the dirt which was all carried up pipe E and delivered to the sewer.

When the tank was emptied, handle C was again forced down. Elbow at the water line also acted as a trap from the sewer when the tank was full of water.



REPAIRING SEWAGE PUMP VALVES.

REPAIRING VALVES IN A SEWAGE PUMP

By John Port

IN a large sewage pump the valve parts A, were screwed into the valve chamber bed B. The ports were as shown so that pieces of cloth and other material could pass through them. The valve covers were made of brass and hinged to a lug at D. In the course of time the parts A became loose and several of them were driven right through the bed B. The only way to fit new valves was to send the pump to the factory as the old threads on the bed were worn out. This would take up considerable time and the sewage tank should be pumped out every 48 hours.

Fine copper wire was turned or tied around the ports A, and they were screwed into place, next two holes were drilled at opposite sides and tapped out for ⅜ bolts at C. C. Two bolts for each valve were made with a slight taper and a very tight fit, and were screwed into the holes as far as possible without twisting them apart, and then sawed off level with the top of the port, the eight valves in the pump were treated in the same way. The pump has been in operation, for several months and is O.K. yet

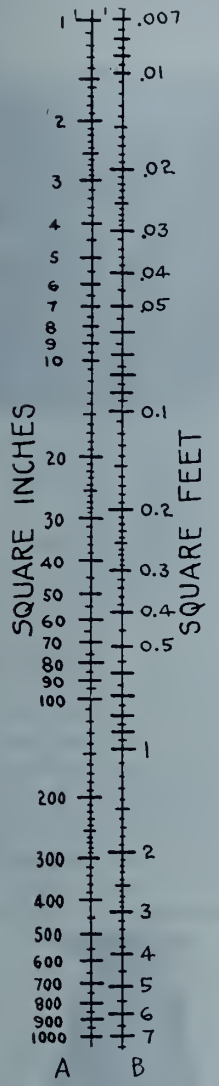
This job saved the owners at least $40, and a possible lawsuit if the sewage had

been allowed to run free while new valves were being made.

CONVERTING SQ. INCHES INTO SQ. FEET

By N. G. Near

ENGINEERS will find this scale handy for quickly converting square inches into square feet, or vice versa. Simply glance across from one column to the other and the answer is immediately found. For example:—How many square feet are there in 300 sq. inches? Find the 300 in column A and glance across to column B. The answer is—practically 2.1 sq. ft. Again, how many square inches are there in 2 sq. ft.?



Find the 2 in column B and glance across to column A. The answer is, of course, 288, but we would call it roughly 290.

The first operation is the one that is most difficult to perform "longhand." Multiplying generally comes more easily, and so the second operation would perhaps be used more often.

CORROSION AND FOAMING

PITTING and corrosion in boilers are frequently due to magnesium chloride in waters and less often to calcium chloride. Either of these salts is very pernicious, in that on hydrolysis it produces free hydrochloric acid. This action is, however, in large measure counteracted when the temporary hardness runs high. In some localities waters are rather high in nitrates, and such waters are always highly corrosive. Large amounts of sodium chloride also tend to make waters corrosive. Some waters that are very low in their mineral content produce corrosion, especially at the feed-water intake, owing to a large amount of dissolved oxygen and free carbonic acid. Peaty waters are harmful to boilers, by reason of the vegetable acids which they contain. Waters containing a free mineral acid are particularly harmful.

Waters which contain large amounts of alkali salts, especially sodium carbonate and sodium chloride, have a tendency to foam. Suspended matter of any kind increases the foaming tendency, and for this reason frequently muddy waters produce this effect, which disappears after the water supply has become clear by sedimentation. Waters low in mineral content but high in organic matter, though perfectly clear, may also be troublesome, because a part of the organic matter precipitates. The bad effect of mineral or vegetable oils finding their way into the boiler feed water is well understood.

One point that should be emphasized in this connection is that sodium salts, in most cases sodium sulphate, are augumented in the softening process. If a water contains magnesium sulphate or calcium sulphate, two important salts in bad boiler waters, they will require soda ash and there will be put into the softened water 142 lb. of sulphate of soda for every 106 lb. of soda ash used. Lime removes the temporary hardness from water without introducing other salts in exchange, while soda ash introduces a corresponding amount of soluble alkali salts. Some waters are so high in initial alkali salts that they will not stand a further addition from the soda ash used as softener without producing serious foaming. In such cases barium hydroxide can be used as substitute for soda ash, although its high cost limits its use to emergency. One other objection lies in the poisonous action of all barium salts that are soluble.

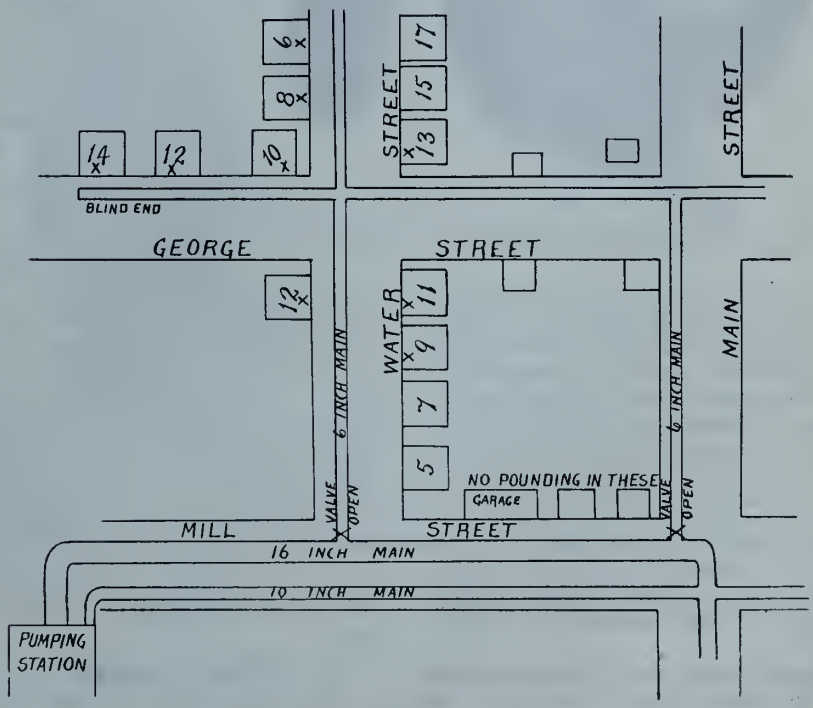
From what has been said relative to the effect of large amounts of alkali salts on waters, it is evident that one good result to be obtained from chemical control in water softening is the prevention of an overfeed of soda ash, as any large excess of this chemical will produce a foaming water. The only methods of combating foaming waters appears to lie in frequent blowing off and washing out the boilers and along lines of improved boiler construction.—A.S.M.E. Paper.

POUNDING IN PIPES OF WATER-WORKS SYSTEM

By W. Carnegie.

THE accompanying diagram illustrates the mains of a water service. Recently, consumers in houses marked by a X have been complaining of a pounding in the water pipes in their houses. The pounding is not continuous and generally commences in the evening. The writer is quite at a loss to account for this trouble. In house No. 7, which is only a short distance from the pump-house the use of an electric tester failed to detect the strokes of the pump, while in No. 9 house the noise is very bad. In house No. 11 the noise is barely audible while in No. 13 it is very bad at times, also Nos. 10, 12, 14, 8 and 6.

Readers who have had experience of similar occurrences are invited to express opinions and offer suggestions to improve the situation.



POUNDING IN PIPES OF WATER WORKS SYSTEM.

Steam Power Plant Auxiliaries

OIL SEPARATORS—I.

IN addition to removing moisture from live steam, separators have an equally important duty to perform in the removal of oil from exhaust steam before it is condensed and used for boiler-feed and other purposes. Where exhaust steam is used for heating, drying, and other allied purposes, the necessity for having it dry is just as strong from an economic point of view as in the case of live steam, as definite observations have proven that condensation in any kind of cylinder or receptacle is more rapid when the steam is wet than when it is initially dry. Although, therefore, an oil separator on an exhaust pipe does not have to handle conditions involving mechanical strains, etc., such as arise from slugs of water coming over with steam from the boilers, it must be so designed as to extract both moisture and oil at comparatively low pressures with correspondingly reduced velocities.

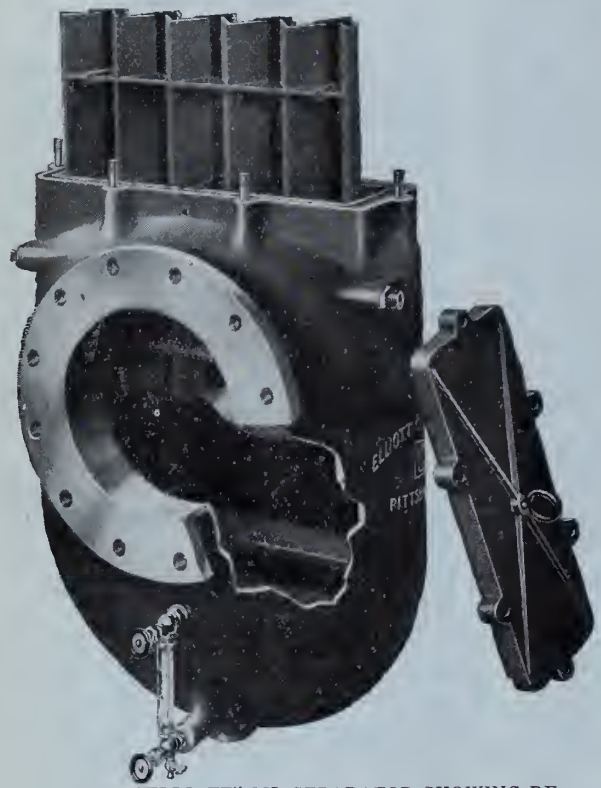


FIG. 1. "ELLIOTT" OIL SEPARATOR SHOWING REMOVAL OF BAFFLE PLATE FOR CLEANING.

Exhaust steam when properly purified and free from oil and moisture, is a prolific source of economy, containing, as it does, 80 to 90 per cent. as much heat as was originally put into the live steam. The condensed returns make ideal boiler feed when free from oil since they possess no scale-making impurities. The evil effects of oil in exhaust steam are well understood. If used for heating, the oil in exhaust steam will in time coat the inner surfaces of the apparatus so as to reduce their efficiency, while condensed returns containing oil should on no account be used for feed-water, as its action on the internal heating surfaces is that of a non-conductor, causing overheating of plates, tubes, and flues, with ultimate bulging, collapsing, or other failure.

Cylinder oil employed for the lubrication of engines and similar steam-operated mechanism, appears in the exhaust steam in two forms, free oil and emulsified oil, partly carried as particles in the steam current and partly mixed with the condensation. The principles employed in the mechanical separation of oil and moisture involve application of the laws of inertia and momentum. Various types of oil separators are in existence, which embody to a greater or less extent three principal features, viz., decrease of velocity, change of direction, and ample reservoir capacity. The first of these is obtained by making the separator head or chamber larger than the pipe, so that the entering steam has its velocity reduced to an extent which allows the force of gravity to exert its influence in withdrawing oil from the steam. The second feature plays a highly important part in nearly all separators and is generally accomplished by baffles, spirals, etc., which produce a whip-like action on the steam and cause the particles of oil and moisture to impinge on variously shaped baffles down which they travel to the receiver space. In some cases water spray is played on the plates to facilitate separation of the oil.

Elliott Separators

The removal of oil from exhaust steam on its way to a condenser presents difficulties that do not exist with non-condensing systems, due to the high velocity of steam resulting from large volume and low pressure.

Fig. 1 illustrates an Elliott type P separator, specially suited for vacuum work. The baffles consist of a double row of V-shaped plates, and the steam, in order to pass through, must make a number of short quick turns, this action effecting the removal of all the oil and entrainment. The first row of plates merely directs the steam at the proper angle against the second row of baffles, which in turn throw the particles of oil back into the recess angles of the first row, thus putting the oil completely out of the path of the steam. If the steam is dry, the baffles are kept wet with jets of water from a spray pipe, connection for which is shown on side of separator, which arrangement not only assists in the separation of the oil from the steam, but in a measure prevents the plates from becoming gummed up in continuous use. As the cover of the separator is removable, the baffle plates

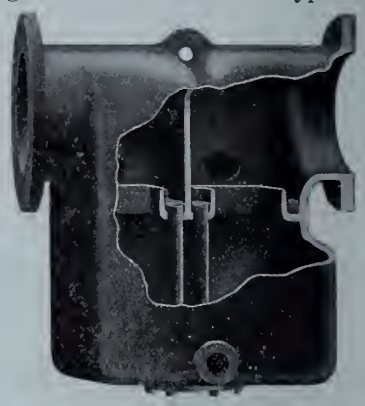

FIG. 2. "HOPPES" OIL ELIMINATOR SHOWING SEPARATING TROUGHS AND LARGE PASSAGES

FIG. 3. "ANDERSON" VERTICAL OIL SEPARATOR SHOWING SPIRAL VANES AND BAFFLE ON OUTLET

can be taken out and cleaned when necessary without breaking connections. These separators are part of the line manufactured by the Elliott Co., Pittsburgh, Pa.

Hoppes Oil Eliminator

In this apparatus special effort has been made to avoid any obstruction to the flow of steam from the engine to the condenser and all possibility of obstruction has been avoided as much as possible. With this end in view, the area of the ports exceeds one and one-half times that of the pipe, small or tortuous passages being conspicuously absent The separation of the oil is thoroughly accomplished by troughs, partly filled with water, which surround both inlet and outlet ports. The reduced velocity and large contact surface of the walls facilitate the separation of the entrained oil, which is also intercepted by the trough surrounding the inlet port, and is thus prevented from being sprayed into the steam chamber by the main current which in its downward plunge carries all suspended oil to the bottom, where it is separated by contact with the surface of the contained water and retained. The outlet port is surrounded by a second

FIG. 4. HORIZONTAL TYPE OF "ANDERSON" SEPARATOR SHOWING RECEIVER CAPACITY

water trough, which cuts off any oil which may tend to creep out on the wall surfaces. An overflow pipe from each trough carries the oil and surplus water to the bottom of the separator, from which another overflow pipe is connected to a receiver or trap.

These eliminators are built in a full range of sizes, horizontal, vertical and right angle, in both cast iron and steel shells by the Hoppes Mfg. Co., Springfield, O.

Anderson Oil Separators

The employment of centrifugal force through the medium of suitably disposed spiral vanes, etc., is one of the principal features of the Anderson oil separator. A cone-shaped cap in the head guides the steam with minimum friction through the spiral vanes shown in transparent view, Fig. 3; these vanes imparting a centrifugal motion to the steam which throws the oil and moisture to the outside of the case, whence it passes down into the receiving chamber. This receiving chamber, which forms the lower part of the casing, contains the outlet opening which is provided with a baffle ring to prevent the oil and moisture from again intermingling with the steam. Both horizontal and vertical types are built in sizes ranging from 1½ in. to 12 in. by the V. D. Anderson Co., Cleveland, O.

Hine Eliminator

Large area of passages, reversal of

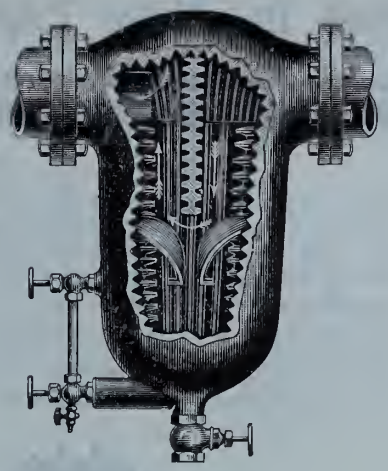

FIG. 5. HORIZONTAL "HINE" ELIMINATOR.

direction and the use of corrugated surfaces for catching the entrained oil and moisture are features of the Hine Eliminator which is illustrated in Figs. 5 and 6. The action in each case is similar. Entering the inlet of the horizontal type, the steam impacts against the central baffle, proceeding thence over and under, in such a manner that the centrifugal force brought into play causes the oil and moisture to be deposited on the adjacent grooved surfaces. Separated matter drains to the bottom down suitably arranged grooves, grooved baffles being placed over the receiver space to maintain separation of drainage. The vertical type, Fig. 6, causes the steam to make two complete reversals in passing over the corrugated surfaces. Separated mat-

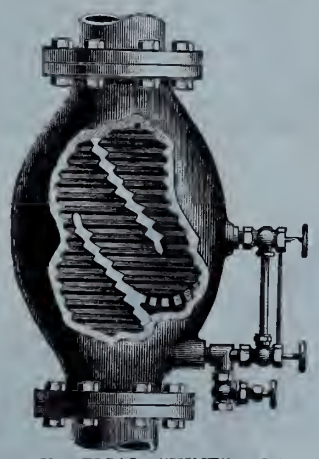

FIG. 6. VERTICAL "HINE" ELIMINATOR.

ter drains into a pocket at the lower right, as shown, whence it passes to receiver or trap. J. L. Robertson & Sons, New York, are the makers of this device.

BOILER FAILURES AND LOSSES DUE TO SCALE

SO much has already been written about scale, corrosion, priming, etc., that it is somewhat disconcerting to note that reports show an increased number of dangerous defects in boilers from year to year due to these causes. A prominent boiler inspector says, "If I were asked to state the most frequent cause of steam boiler explosions, meaning the tearing asunder of any part of a boiler by force of steam pressure, I would unhesitatingly say it is scale."

If the water in a boiler comes in direct contact with the hot plates or tubes, these, if free from scale, remain practically at the same temperature as the water. If there be a greater or less thickness of scale on the plates, however, the scale acts as a very poor conductor of heat, and the iron plates and tubes may reach a plastic temperature because the water does not absorb the heat from them, and they may finally fail, due to the force of the steam pressure in the boiler.

Aside from the possible dangerous condition of a "scaly" boiler, the fact must be borne in mind that scale means fuel waste. Authorities differ on the exact amount of such waste, but a general average of experimental evidence on this point is shown in the following:

Thickness of scale, in. 1-64, 1-32, 1-16, ⅛, ¼, ½, ¾.

Waste of fuel, per cent. 2, 4, 9, 18, 38, 60, 90.

It is undoubtedly true that the physical and chemical characteristics of the scale formed have something to do with its nonconducting properties, and it is believed to be quite unlikely that the extreme losses shown would be met with in practice.

There are other scale troubles than those enumerated above. Scale may clog feed pipes and water and steam gauge connections, and prevent the complete closing of valves. An instance is recorded where the blow-off valve was presumed to be closed completely, but had a piece of scale under it; the water slowly leaked out, and this fact, necessarily coupled with a lack of proper attention to the boiler caused the plates and tubes of the boiler to be burned to a proper condition for the junk heap.

These statements and the general mass of evidence now extant in power-plant literature show that it is to the best interests of owners and operators to keep boilers practically free from scale for reasons of safety, economy of fuel, saving of labor, and durability.—A.S.M.E.

KEROSENE A REMEDY FOR SCALE TROUBLES

THE use of kerosene oil as a remedy for scale troubles has had many advocates, and its success, while undoubtedly due to mechanical action alone in removing scale and preventing its formation, depends upon conditions and upon the user. To be reasonably effective in any case, the kerosene should be put in after the boiler is emptied and washed, and the refilling of the boiler be slowly done from the bottom. It is useless to pump the kerosene in with the feed water, for, like the heavier oils, it may tend to form a nonconducting film over the heating surfaces that will introduce an element of danger in operation.

Progress in New Equipment

COMBINED STEAM TURBINE AND CENTRIFUGAL BOILER FEED PUMP

THE tendency towards displacement of the reciprocating boiler feed pump by the centrifugal pump furnishes a good example of the necessity resting upon manufacturers of machinery for sustained technical development. Since it must handle a comparatively small amount of water against a relatively great head, the centrifugal boiler feeder should be fitted with small diameter impellers running at high speed. It is therefore well adapted for steam turbine drive. Fig. 1 shows an early steam turbine-driven boiler feeder built in 1910 by the De Laval Steam Turbine Co. The two-stage pump has a capacity of 1,600 gals. per minute against 700 ft. head at 2,800 r.p.m., and upon test gave an efficiency of 60 per cent. The pump is entirely independent of the turbine, a coupling being interposed between the pump shaft and the turbine shaft, and it could therefore have been driven just as well by electric motor or by rope or belt as by a steam turbine.

The unit, however, realized the advantages peculiar to the centrifugal boiler feeder, viz., reliable and uninterrupted service with little, and often unskilled attention, absence of pulsation, shock, water hammer, vibration, or over pressure in pipe lines, elimination of relief valves, suitability for use with automatic boiler feed regulators acting independently at each boiler and with feed water meters, close governing, either by speed governors or by pressure governors, freedom from injury by overloading, lightness and compactness, accessibility, elimination of valves, packings, sliding surfaces and air chambers, small upkeep and attendance expense due to simplicity and few wearing parts, lower cost of maintenance of piping system, small consumption of oil, efficiency, and in the turbine-driven type, ability to use superheated steam or to run upon either high or low pressure steam, oil-free exhaust, and independence of the main units.

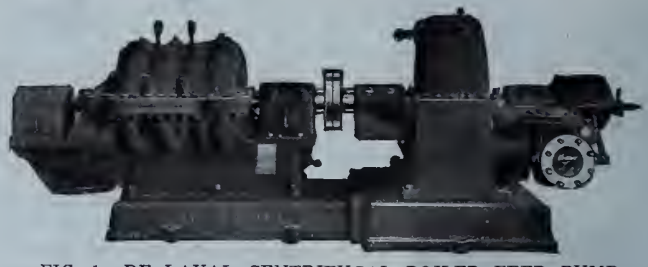

FIG. 1. DE LAVAL CENTRIFUGAL BOILER FEED PUMP COUPLED TO INDEPENDENT TURBINE.

A still further development in the direction of compactness and simplicity is shown by Figs. 4 and 5, illustrating a 3,000 horse-power, two-stage centrifugal boiler feeder combined in one casing and on one shaft with a velocity-stage steam turbine. This unit, which also has been developed by the De Laval Steam Turbine Co., weighs, it is claimed, about one-tenth as much as a duplex reciprocating pump of the same delivery and occupies only about one-eighth as much floor space and one-fifteenth as much cubical space.

The pump end contains two single-suction impelelrs cast from a special bronze and carefully finished to exact contours. Two impellers are used for pressures up to 200 lbs. per sq. in., and three impellers for higher pressures. Single-stage boiler feed pumps have been built, but two or three stages are preferable because of the much longer life of the impellers at slower speeds. Each impeller discharges into a volute chamber by means of which the velocity in the water as it leaves the impeller is converted into pressure before the water is led to the eye of the succeeding impeller. This means of energy conversion is claimed to be superior to the use of diffusion rings as it is efficient over a wider range of delivery, and more important still, does not involve the use of small and sharp parts like diffusion blades, which are subject to rapid erosion.

The pump is hydraulically balanced and only one pair of labyrinth rings surrounding the suction opening is required for each impeller except the last, which has two sets of rings. The whole back of the impeller is subjected to a pressure equal to that existing at the periphery of the impeller, the same pressure acting on the front of the impeller, except for the area of the circle enclosed by the labyrinth ring about the suction opening. The last impeller, that is the one from which the water is finally dis-

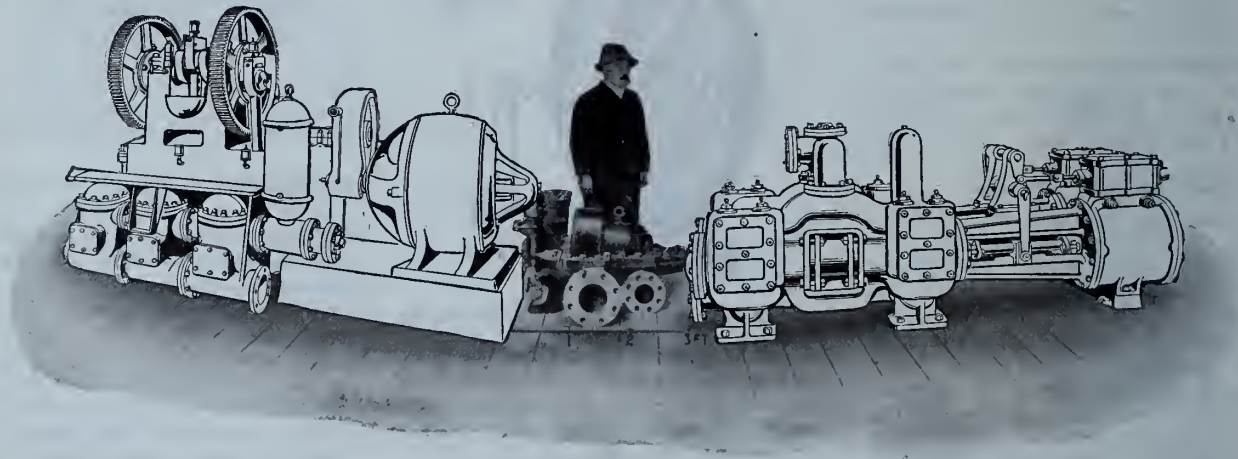

FIG. 2. COMPARATIVE CAPACITY DIAGRAM SHOWING STEAM TURBINE-DRIVEN BOILER FEED PUMP, DUPLEX STEAM PUMP, AND TRIPLEX MOTOR-DRIVEN PUMP.

charged, is equipped with two sets of wearing rings, one on the suction side and one on the reverse side of the web. As some water from the discharge of this impeller will leak between the wearing rings into the space back of the web, this impeller would be equally as unbalanced as the other impellers in the pump if there were no escape for the leakage water. To provide for diminishing the pressure in this balancing space as much as may be required to bring the whole series of impellers into balance, a leakage outlet is provided from which water can be conducted back to the suction of the first impeller.

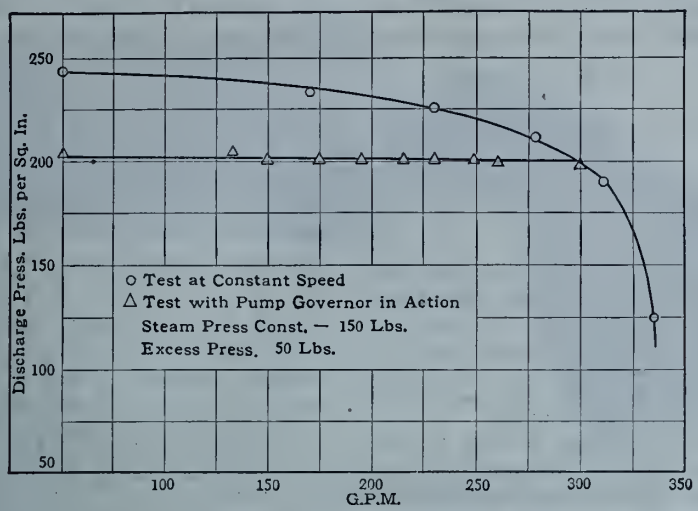

FIG. 3. HEAD DELIVERY CHARACTERISTIC OF DE LAVAL TURBINE-DRIVEN BOILER FEED PUMP UNDER CONTROL OF SPEED AND PRESSURE GOVERNORS RESPECTIVELY.

The outlet leakage takes place between two collars, one attached to the casing and the other carried on the shaft. When the shaft moves towards the discharge end of the pump this escape is closed off and the pressure builds up in the balancing chamber. If the shaft, on the other hand, moves toward the suction, this escape passage is opened wider, allowing the pressure in the balancing chamber to fall and at the same time the inleakage between the labyrinth wearing rings is decreased. By this means direct and positive balancing within very close limits is secured with leakage of but a small amount of water. The so-called natural balancing secured by the use of double suction impellers in a multi-stage pump is in comparison uncertain and imperfect, besides involving an extra long shaft, heavier impellers, and two pairs of wearing rings to each impeller.

The labyrinth wearing rings are readily renewable, the stationary ring of each pair being held in seat in the casing and the rotating ring being screwed upon the impeller. The reduction of leakage secured by the use of intermeshing labyrinth rings is highly important for securing high efficiency in pumps of comparatively small delivery. With the labyrinth type of ring the leakage path is so tortuous that very little water escapes even at high heads, although ample clearance is provided to take up expansion and contraction due to changes in temperature.

The suction end of the pump is adjacent to the turbine, and the shaft packing between the turbine and pump chambers is hence subjected to turbine exhaust pressure on one side and the suction pressure on the other. A simple packing is therefore sufficient, and in any case, any small leakage of steam in one direction or of water in the other does no harm. As the leakage space adjacent to the balancing chamber at the discharge end of the pump is connected back to the pump suction, the packing about the shaft is subjected only to suction pressure. Aside from the intermediate packing already mentioned, there is only one steam packing, which is subjected to exhaust pressure.

The steam end of the unit consists of a velocity- stage turbine with either two or three rows of moving buckets, according to the steam economy desired. The nozzles can be proportioned for either high pressure steam exhausting to feed heater or to condenser or for low pressure steam exhausting to condenser, or the unit can be made interchangeable, thus permitting of a great degree of flexibility in plant design. Where the exhaust steam from the boiler feeder is consumed in heating feed water, the thermal efficiency of the turbine- driven boiler feeds is greater than that of a boiler feeder driven by electric motor, or even than that of the main unit itself.

The unit is in some instances fitted with a speed governor mounted upon the end of the shaft, and when running at constant speed, the head varies with the delivery, as shown by the curved characteristic in the accompanying chart. As will be seen, the rise in pressure at reduced capacity is not excessive. Ordinarily, however, a pump governor controlled by the pressure at some point in the feed line near the boilers is employed to control the speed, giving a practically uniform pressure at all deliveries, as shown by the lower and straight line in the chart. In case of failure of the pressure governor to operate. the control of the unit is automatically taken over by the speed governor.

However, to provide against any possibility of racing, an emergency governor is also fitted. This consists of a pin contained within a hole bored diametrically through the shaft. This pin is held by a spring from flying out under the influence of centrifugal force. When the speed reaches a certain point, the spring is compressed so that the pin strikes a trip, releasing another spring by which the governor valve is closed at once and completely. Racing and excessive over-pressure are therefore impossible. The normal speeds of these pumps vary from 1,800 to 3,500 r.p.m., according to pressure and capacity, and

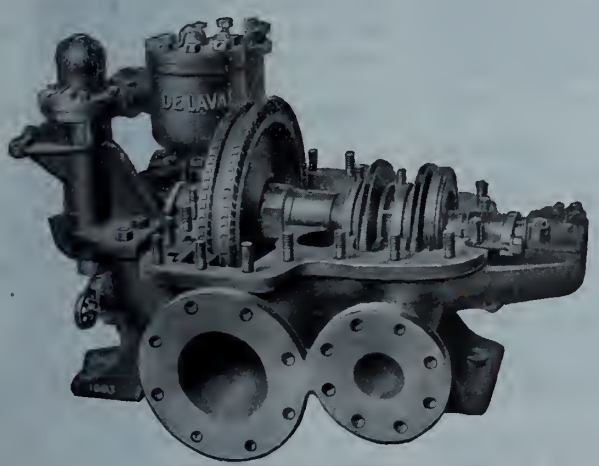

FIG. 4. DE LAVAL COMBINED TURBINE-DRIVEN BOILER FEED PUMP. CAPACITY 3,000 BOILER-HOUSE POWER.

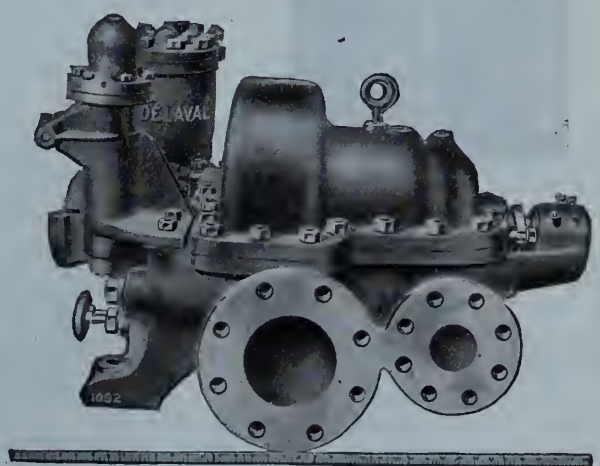

FIG. 5. DE LAVAL COMBINED TURBINE-DRIVEN BOILER FEED PUMP WITH CASING COVER REMOVED.

due to the heavy shafts employed are far below the critical speeds.

The bearings are of the straight, split ring-oiled type, and like other parts subject to wear, such as the pump impellers, turbine rotor labyrinth rings, and governor valves, are built to a limit-gauge basis, so that they are all interchangeable. The entire rotating members and all wearing parts, with the exception of the governor valve, are accessible for inspection or removal upon lifting the casing cover and taking off the bearing caps, all of which can be done without breaking steam or water pipe connections.

In specifying the capacity of boiler feeders ,the temperature of the water to be pumped should always be stated, as the capacity is nearly 50 per cent. greater with water at 75 deg. F. than with water at 210 deg. F. For the same reason, capacity and efficiency tests of a pump should be carried out with water at the temperature at which it will be received by the pump when in actual service. The De Laval Steam Turbine Co. inform us that they are equipped to make such tests on all pumps that it builds.

CELL MOUNTING OIL CIRCUIT BREAKER

A COMPLETE line of oil circuit breakers has been recently developed by the Westinghouse Electric & Mfg. Co., East Pittsburgh, two of which, types E6 and E7, range in capacities from 300 to 1,200 amps. at 23,000 volts, and from 1,600 to 2,000 amps. at 16,500 volts. The former is for cell mounting, as illustrated in the accompanying engraving, while the latter is for wall or pipe mounting. All

SHELL MOUNTING OIL CIRCUIT BREAKER.

steel construction is used, thus providing apparatus which is exceptionally compact for its rupturing capacity, which ranges from 35,000 to 40,000 kva. at maximum rated voltage, with proportionately higher capacities for lower voltages.

For cell mounting, a novel feature is the holding of the steel base of each pole unit in channel irons built into the cell walls, whereby the units are easily slid in and out; the single pole solenoid complete with its mechanism, is mounted on top of the cell structure. Accelerating springs are provided to break the arc as quickly as possible after the breaker starts to operate, an adjustable air cylinder dash pot being furnished to take up the shock of the moving parts.

All breakers are able to clear the system of a short-circuit up to its rated capacity three times without attention to circuits, a test of sixteen breaks being made on a 25,000 kva., 23,000 volt turbo-generator circuit, without the breaker being opened for change of arcs.

BOILER TROUBLES CAUSED BY CORROSION

SCALE is not the only source of boiler trouble caused by water, the trouble due to corrosion of sheets, tubes, stays, etc., being in some cases more acute than ever occurs with scale. Carbonic acid gas, occluded oxygen, and sodium and magnesium chlorides are the most frequent offenders in this respect, and the chlorides are so difficult to remove from the water as to make the cost of removal practically prohibitive.

Corrosion due to the chloride ingredients is particularly destructive to steel boiler tubes, hot-water piping, and brass-seated valves. Galvanized steel pipe is not immune to the action of these salts, because any defect in the zinc coating permits the setting up of local galvanic action between the zinc and steel in the presence of salt water, with the consequent rapid destruction of the zinc coating. Water which contains as much as five hundred parts per million of either or both of these chlorides, as is sometimes the case with deep well water, may be regarded, especially when hot, as a water destructive to steel pipe and fittings.

In the writers' experience several steel deep-well casings have corroded through after having been placed but a few years, and permitted salt water from another stratum to enter the wells and practically ruin their waters for boiler purposes and hot-water lines. The remedy in a number of such cases has been to place another casing inside the original one, using genuine wrought-iron pipe, and at the same time pack off the salt water effectively by means of hemp-rope coils placed on the new casing. Genuine wrought-iron pipe and fittings will unquestionably outlast any steel pipe under such conditions.

Waters are frequently both scale-forming and corrosive; usually, if a water has a corrosive tendency there will be scale formation to a greater or less extent. Caustic or carbonate alkalies or caustic lime act as neutralizing agents for corrosive ingredients, but these reagents must be carefully handled or the scale-forming matter will be greatly increased, and their use should be confined to treatment of the water outside the boiler if possible.

Owing to the ordinary varying pressures on different parts of the boiler, especially when blowing off rapidly under high steam pressure, as is sometimes done, the mechanical movement of the sheets is likely to assist corrosion to complete a failure of the boiler, in that, in some cases, sheets bulge and seams open, allowing water or steam to leak through and cause abrasive action which supplements the corrosive action and is sometimes mistaken therefor.

Cases of corrosion in fire-tube boilers which have come within the observation of the writers would indicate the corrosive action to be variable in character; in some cases the pits were small depressions; in others, large, cup-shaped hollows, and in one instance the main corrosive action had taken place at about the average height of the water line along the shell; the shell was eaten through completely and a leak started while the boiler was under 150 lb. steam pressure. Soon afterwards, when this boiler was removed from its setting and discarded, it was easily possible to break through the shell with a 2-lb. hammer along the line mentioned. Official inspection of the boiler had been made by the insurance company inspector but a few weeks before, and no defect was indicated in the report concerning it. This practical illustration, which is but one in line with many referred to from time to time in technical papers, of the impossibility of thoroughly inspecting a fire-tube boiler without the removal of at least a part of the flues, is a most important indication of the desirability of careful attention to the purification of boiler water.

It is true that the safety feature is of much less moment with water-tube boilers than with fire-tube boilers, but the price of water-tube boilers is necessarily higher for a given capacity, and under all-day operating conditions their increased efficiency over fire-tube boilers is not of consequence for small power plants up to about 600 h.p. With bad water the water-tube has the advantage, in all but a few types, of being readily inspected. Someone has estimated that three times the labor is required to clean a foul water-tube boiler than is necessary for a fire-tube boiler of the same capacity, but the fact should be emphasized, nevertheless, that one can thoroughly clean a badly "scaled" water-tube boiler, but he cannot as thoroughly clean a badly "scaled" fire-tube without using an extraordinary method and incurring extra expense.—A.S.M.E. paper.

PRODUCTION OF COMBUSTION OF COAL

When carbon burns completely the product is carbon dioxide (CO_2); when it is partly burned the product is carbon monoxide (CO). If more oxygen is supplied, carbon monoxide can be burned to carbon dioxide. The hydrogen of coal burns to water vapor, which condenses to water when cooled to atmospheric temperature. The furnace gases therefore consist mainly of oxygen (O_2), nitrogen (N_2), carbon dioxide (CO_2), and carbon monoxide (CO). Besides these there may be found near the surface of fuel bed a small quantity of hydrogen (H_2), methane (CH_4), and unsaturated hydrocarbons. By analyzing the gases at successive points in a furnace the progress of combustion can be studied.

THE BULLDOG WINS

When it comes to staying on a hard job there is no cleaner like the old reliable "BULLDOG."

The "BULLDOG" Cleaner for bent tubes — operated by water.

Another Cleaner Fell Down

In a certain plant in Missouri the only day that a boiler could be spared for cleaning was on Sundays when the load on the plant was light. The engineer tried in vain to keep the boilers clean by working hard all day Sunday, but the best he could accomplish with the cleaner he had was an average of ten tubes per Sunday. This was far from enough, as the condition of his boilers was getting worse and worse.

Then in some manner he heard of our "Bulldog" cleaner (perhaps through an ad. similar to this). After an investigation a "Bulldog" was ordered. The first Sunday's work with the "Bulldog" resulted in the removal of more than 2,000 lb. of scale from a 300-hp. Heine Boiler and the boiler was entirely cleaned—ready to go back in the line—at six o'clock in the evening. Boiler cleaning, even under the most favorable conditions, is a hard proposition, but the "Bulldog" Cleaner goes a long way toward making the task less difficult. It has no rival either for speed or endurance, which are the important factors when a boiler is down for cleaning.

Catalog "H" describes the "Bulldog" Cleaner, also the "Victor" and other types. Send now for a copy and have it on hand when it is wanted. It's yours for the askin'.

LIBERTY MANUFACTURING COMPANY

6904 Susquehanna Street **Pittsburgh, Pennsylvania**

Just as the "Bulldog" is the King of the water operated tube cleaner, the "Victor" is the Premier of the tube cleaner operated by air or steam. The "Victor" shown below is made in all sizes suitable for all type of boilers.

The "VICTOR" Cleaner —for straight tubes — operated by air or steam.

The illustration below shows the result of 3-in. "Bulldog's" battle with scale. This "Bulldog" run continuously for 480 hours without any repairs, except drill points.

If any advertisement interests you, tear it out now and place with letters to be answered.

Projects and Developments

TRADE GOSSIP

E. T. Austin has been appointed manager of the Belleville Waterworks Department in succession to J. W. Evans.

Montreal, Que.—The Riordon Pulp & Paper Co., contemplate developing water powers at Hawkesbury and Merritton, Ont., aggregating 30,000 h.p.

Prince Rupert, B.C.—The City Council are considering the question of installing a cold storage plant to aid the fishing industry.

Thomas J. Gerry who for over twenty-five years was connected with the Dodge Manufacturing Co., Toronto, as traveller died at his home in Toronto recently.

Sudbury, Ont.—The Town Council propose to spend $46,000 for a stand pipe and auxiliary water main, and $2,500 for alterations to the lake sewer pumping station.

Yorkton, Sask.—Tenders will be received until April 30 for one 350-400 b.h.p., combined Diesel electric unit. Specifications may be obtained from F. J. Pilkington, Town Clerk.

Redcliff, Alta.—An expenditure of $30,000 is contemplated for alterations in the present pumping station and installation of adequate machinery. A by-law will be submitted to ratepayers.

Sudbury, Ont.—On April 30 a by-law will be voted on by the ratepayers to sanction an expenditure of $46,000 for stand pipe and auxiliary main, and $2,500 for alterations to lake sewer pumping station. W. J. Ross, town clerk.

Toronto, Ont.—The Hydro-Electric Commission contemplate a further development of 1,500 h.p. at Eugenia Falls and 2,000 h.p. at Big Chute. The proposed expenditure for Eugenia Falls extension is placed at $217,897, and that for the Severn River extension $121,238.

The Bawden Pump Co. has been incorporated at Toronto, with a capital of $40,000, to carry on the business of engineers and founders, including the manufacture of pumps of all kinds at Toronto. The incorporators are: G. H. Sedgewick, James Aitchison, and Duncan McArthur, all of Toronto.

The Turbine Equipment Co., Toronto, have been awarded a contract by the Union Carbide Co., of Niagara Falls, N.Y.; and Welland, Ont., for three De Laval single stage, double suction, pumps, of 3-million, 2-million and 1-million gals. daily capacity respectively, to be motor driven.,

Aylmer, Ont.—At a meeting of the Town Council on April 2, a bylaw to borrow $29,000 for Hydro power by the issue of debentures was passed, $22,000 being the amount to be set apart for the remodelling of the electrical distribution system and $7,000 for the installation of an electrically-driven pump, a gasoline pump or an electrically-driven fire pump. A by-law will be submitted to the ratepayers on April 30.

The Turbine Equipment Co., Toronto, have been awarded a contract by The Imperial Oil Co., Church St., Toronto, to supply for their new plant at Dartmouth, N.S., 13-De Laval single stage, double suction pumps, ranging in size from 1500 gals. to 350 gals. a minute. The Imperial Oil Co., have also placed another order for two additional single stage, double suction, high lift De Laval pumps, each to be direct connected to 150 h.p. motors.

Lieut.-Col. Wood Leonard, D.S.O., of London, Ont., was killed in action recently in France, while in command of the 3rd Artillery Brigade. Col. Leonard was a son of Frank E. Leonard, and was associated with his father and brothers in the firm of Leonard & Sons, the well known engineers of London, Ont. He was a graduate of the Royal Military College, Kingston, Ont., and went overseas in 1914 in command of the 6th Field Battery. Col. Leonard was 34 years of age.

The Turbine Equipment Co., Toronto, have received a contract amounting to $19,000 to supply and install, 8-De Laval single stage, double suction centrifugal pumps, for the new filtration plant for the town of St. Hyacinthe. One will be 5 million Imperial gals. daily unit, another 4½ million gals. daily, and there will be 6 having capacity of 2½ million Imperial gals. daily. All these pumps will be connected direct to Canadian Westinghouse motors. They will also supply 40 h.p. motor driven Roots blower, complete switch-board etc.

The Turbine Equipment Co., Toronto, has been awarded a contract by the town of Strathroy, Ont., for one multi-stage De Laval centrifugal pump, which will be direct connected to a Canadian Westinghouse 125 h.p. motor; the capacity will be 1,000 Imperial gallons a minute, against 252 ft. total head. They have also been awarded through the Hydro-Electric Power Commission of Ontario one De Laval single stage, centrifugal pump, which will have a capacity of 5,000,000 Imperial gallons a day against 210 ft. total head. This pump is for the City of Kingston, Ont., and will be direct connected to a 380 k.v.a. Canadian General Electric 1,200 r.p.m. synchronous motor.

CATALOGUES

Sight Feed Lubricators.—Two bulletins have been issued by the Penberthy Injector Co., Windsor, Ont., describing and illustrating the "Peerless" and new "Polar" sight feed steam lubricators.

Ball Bearings.—The Rochester Ball Bearing Co., Inc., Rochester, N.Y., have issued Bulletin No. 10, which is a descriptive price list covering the "Rochester" ball thrust bearings. The bulletin contains a description of the bearings and tables giving the principal dimensions and prices.

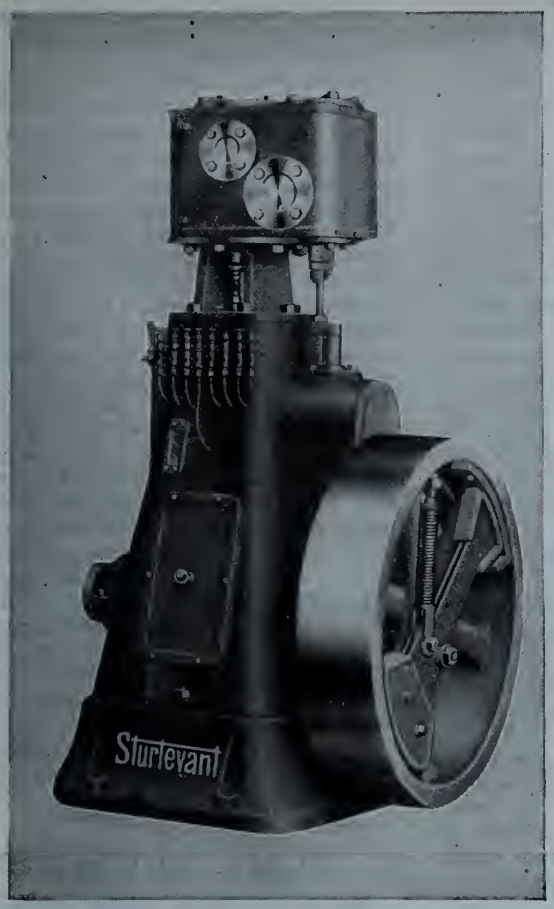
Circulating Pumps.—A bulletin dealing with a line of circulating pumps for machine tools, has been issued by C. F. Roper & Co., Hopedale, Mass. The principal features of construction and method of operation on the Roper geared pump are described fully, accompanied by illustrations which include dimensioned diagrams for various sizes.

The Homestead Valve Mfg. Co., Homestead, Pa., are distributing a bulletin bearing the title "Safety First, then Efficiency, then Economy," having reference to the Homestead line of valves. The "Hovalco" blow-off valves and "Homestead" quarter-turn valves are also illustrated and described.

Hydraulic Presses.—An interesting and varied line of hydraulic presses is described and illustrated in a series of leaflets distributed by the Charles F. Elmes Engineering Works, Chicago, Ill. The principal dimensions are given for the various sizes of each type, and also of equipment used in their operation such as hydraulic pumps, valves, etc.

Automatic Plate Valves.—The Mesta Machinery Co., Pittsburgh, Pa., are distributing a new bulletin dealing with the Mesta automatic plate valves (Iversen Patent). The principal features and general construction of the Mesta valve are described in detail accompanied by illustrations. The suitability of this valve for use in air and gas compressors and blowing engines is mentioned in this bulletin.

Taylor Power Dump.—Catalogue issued by the American Engineering Co., Philadelphia, Pa., describing the Taylor power dump for use in conjunction with the Taylor mechanical stoker. The construction of this power dump and re-



Sturtevant
(Trade Mark)

Vertical Engines

Admirably adapted to isolated installations because entirely enclosed, automatically lubricated, and requiring very little attention.

Compact—quiet in operation—and dependable in the highest degree.

Built in a wide range of sizes and with either forced feed lubrication or automatic gravity lubrication through sight feed glasses.

Described in Bulletin 218-E.

BOILER SCALE Never Was NEUTRAL

It is always on the offensive, coating the shells and tubes of the boiler and greatly lowering the boiler steaming efficiency.

DIXON'S PIONEER BOILER GRAPHITE

is flake graphite. Flake Graphite is the "sapper" that undermines and penetrates the scale at the time of its formation.

Dixon's Pioneer Boiler Graphite attacks scale on all sides, rendering it easy to remove when a cleaning tool is used in the ordinary way.

One engineer effected a saving in cleaning cost of 28¾c on each boiler tube by using "Dixon's Pioneer" method.

sults accomplished by it are described while the method of operation is graphically explained by means of a number of illustrations.

The American Pulley Co., Philadelphia, Pa., have issued a booklet entitled "Building 25," descriptive of a new building recently opened at the plant for the convenience of workmen and for safeguarding their health. The booklet contains descriptive matter, and also a series of photographic views showing the principal features of the building, embodying the latest ideas applied to the preservation of health in factories.

A. C. Generators.—T. W. Broadbent, Ltd., Huddersfield, England, have issued a new bulletin, No. 4, dealing with their T. Type three-phase generators, designed especially for motor driving. A full description is given of this machine, accompanied by illustrations, while a price list is included, giving capacity and weights for each size of generator and exciter. Copies of the bulletin may be obtained on application.

Water Heaters.—The Alberger multi-head water heater for hotels, office buildings and factories, is described in a Bulletin No. 201 recently issued by the Alberger Heater Co., Buffalo, N.Y. The principal constructional features of the multi-head heater and their advantages are described fully, special reference being made to the method used in the heater to accommodate unequal expansions. The bulletin is illustrated.

Row & Davis, Engineers, Inc., 90 West street, New York, have just published two interesting bulletins, copies of which will be mailed to readers on request. "The R. & D. Paracoil "Evaporator," Bulletin No. 51, for single or multiple effect operation. The bulletin shows and describes the evaporator thoroughly. The most interesting feature, perhaps, is the patented new type of manifold, which is mounted on a hinged door to facilitate inspection, cleaning, etc. Bulletin No. 52, "The R. & D. Feed Water Heater" fully describes the shell, manifolds, coils, connections and fittings of their heater. These bulletins should be in the hands of every engineer interested in feed water heating and water distillation.

Dynamos and Motors.—Pamphlet No. 21-C, recently issued by Bruce Peebles & Co., Ltd., Edinburgh, Scotland, illustrates and describes the "Peebles" self-contained continuous current dynamos and motors. A full specification is included covering these machines which are made in various types such as protected type, semi-enclosed, totally enclosed, mining or pipe ventilated type. The first half is taken up with the specification, while in the latter half very complete lists of output ratings are given for the usual standard voltages, and for every size of machine which they manufacture, separate output ratings being given for each of the five different types enumerated above. To assist intending purchasers in laying out their plant, there are also given two pages of approximate weights and dimensions, while on the last page there is an illustration of two machines mounted together, and arranged as an ordinary motor generator, booster or three-wire balancer. Copies of this pamphlet will be gladly sent to anyone interested.

Ball Bearings for Transmission. — The Chapman Double Ball Bearing Co., of Canada, Ltd., Toronto, have issued to the trade a new 48-page bulletin No. 107. This bulletin, which is a very attractive publication, illustrates and describes fully, a standard line of power transmission bearings. Among the illustrations are included a number of sectional views of bearings showing the principal features embodied in their design. The section of the bulletin devoted to the development of the Chapman double ball bearing contains much useful information covering the design and scientific features of this bearing, while details of tests are also included with views of the apparatus used for the tests. The application of ball bearings for loose pulleys and pillow blocks is also dealt with, fully accompanied by dimension tubes and price lists. One interesting feature comprises a number of excellent full page half-tones, showing a variety of power transmission installations equipped with the Chapman product, and also interior views of the company's plant.

BOOK REVIEWS

Mechanical World Pocket Diary and Year Book for 1917, 453 pages, 6 in. x 4 in. Norman Remington & Co., Baltimore, Md. Price 40 cents post free. The 30th annual issue of this year book, published by Emmot & Co., Manchester, contains several new features, while the book generally has been thoroughly revised. The section on steam and the steam engine has been rewritten. New tables have been introduced, giving dimensions of piston rings, governors, etc., while notes on lubrication and anti-friction bearings are now included. A new section on the heat treatment of steel has been introduced, including notes on annealing, hardening, tempering, etc. Other new matter includes tables, giving dimensions of flanged couplings and calculation of springs. Much recent information is also given regarding design of prime movers, boilers, power transmission, machine shop practice and materials. A 57-page diary and memoranda is a useful feature of this publication.

Water Powers of Manitoba, Saskatchewan and Alberta, a well-bound and attractively illustrated volume, just issued by the Commission of Conservation, forms a valuable contribution to the authentic literature respecting the natural resources of Western Canada. This report, by Leo G. Denis and J. B. Challies, comprises the results of special surveys by the Commission of Conservation and a compilation of records from other reliable sources. As a compendium of all available data on the subject, it is particularly valuable

for reference purposes. While the Prairie Provinces, as a whole, are not lavishly endowed with water powers, the report demonstrates that the utility of their rivers for power development can be vastly enhanced through proper storage of flood waters. At present, in the absence of conservation dams, and of adequate natural regulation, the great volume of flow is lost during high water seasons. Methods of development to ensure the maximum utilization are now being carefully worked out on the Winnipeg, Bow and other large rivers. The more northerly regions possess numerous sites of great potential value for pulp, electro-chemical and other special industries. The report just issued is the second in the series on water powers in Canada to be published by the Commission of Conservation. The third volume, "Water Powers of British Columbia," which is now in press, will complete the Commission's general inventory of this item of the Dominion's natural wealth.

"Combustion in the Fuel Bed of Hand-fired Furnaces," is the title of Technical Paper 137, by Henry Kreisinger and others, which has just been issued by the Bureau of Mines of the Department of the Interior, Washington, D.C. The main object of the investigation was to determine the conditions governing the process of combustion in the fuel bed of a hand fired furnace. The results of this investigation furnish data for correct design of coal-burning grates and furnaces and their efficient operation. They also cast light on the important problem of clinker trouble as related to fusibility of ash. They further indicate the possibility of a high rate of gasification of coal in gas producers. The first part contains general information on the combustion of coal in furnaces. The second part contains the description and the results of about fifty tests made in a small experimental hand-fired furnace, which was designed for an accurate study of the processes of combustion in the fuel bed. The third part discusses the investigations described in the second part of the report, and includes about forty charts that show the composition of the gases and the temperature at different depths in the fuel-bed of a hand-fired furnace, and various relations between the air supply and the rate of combustion. The fourth part contains miscellaneous data on the composition of gases rising from the fuel bed of a hand-fired furnace under a steam boiler, a Murphy stoker, and a Jones underfeed stoker. Copies of this technical paper may be obtained free of charge by addressing the Director of the Bureau of Mines, Washington, D.C.

CLASSIFIED ADVERTISING

WANTED—A GOOD SALES ENGINEER to open office to sell Moline heat in Canadian territory. Must be a good salesman, having had a general heating and ventilating experience. Must give good references. We have a fine proposition for the right man. Address Moline Heat, Moline, Ill. ctfm

Trap Every Steam Line with a SARCO

High Cost of Steam

versus

Low Cost of Trapping

There was a time when steam was cheap. Not now. Now it costs more than at any time within a hundred years.

There was a time when all steam traps were expensive, big, cumbersome, troublesome things.

Not now. Now you can use the Steam Trap SARCO, which is small, low-priced, absolutely efficient and reliable, and goes right on any line anywhere.

Many untrapped lines steal the cost of a Sarco every week.

The Steam Trap SARCO relies on the expansion of a heavy hydrocarbon oil operating a Sarco Spiral Tube with a renewable cartridge. When steam reaches the cartridge, the trap closes and no steam escapes. When condensation collects the trap opens and discharges it.

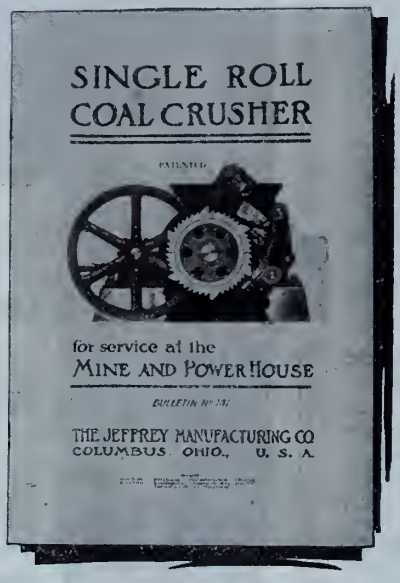
How to Secure a Constant Supply of Right Sized Stoker Coal at a Minimum of Cost? ↓



You will find the answer by reading this book — describing in detail the Design and Construction of the

Jeffrey Single Roll Crusher

the machine which will crush more coal with less power and expense than any other on the market.

A single operation will reduce run-of-mine coal to ¾ or 1 in. (the proven size for maximum stoker efficiency) **in a single operation.**

This book also contains many splendid testimonials from many users, as well as drawings and suggestions as to the ways in which the crusher can be installed in connection with various types of elevating and conveying machinery.

If your power plant is not equipped with the Jeffrey Single Roll Crusher, you are overlooking the most important element in your fuel expense. Fill out the coupon and get a free copy of this interesting book.

Mechanical Regulation of Boiler Feed Water

By the use of the "S-C" method you are assured of a continuous feed at all times load is on boiler. The graduation in rate of feeding is entirely dependent upon the load and fire conditions. The Regulator will carry a constant level on steady load—higher level on light load and lower level on peak loads. Variation in water level is entirely dependent on inclined position of generator which is adjustable while operating under full load.

Bulletin No. 80 explains all.

Generator or Actuating end of Regulator.

Regulating Valve Placed at Any Point, Any Position.

The "S-C" Regulator Company

Feed Water Regulation Engineers

FOSTORIA, OHIO, U.S.A.

It may never happen to you—but are you SURE it WON'T?

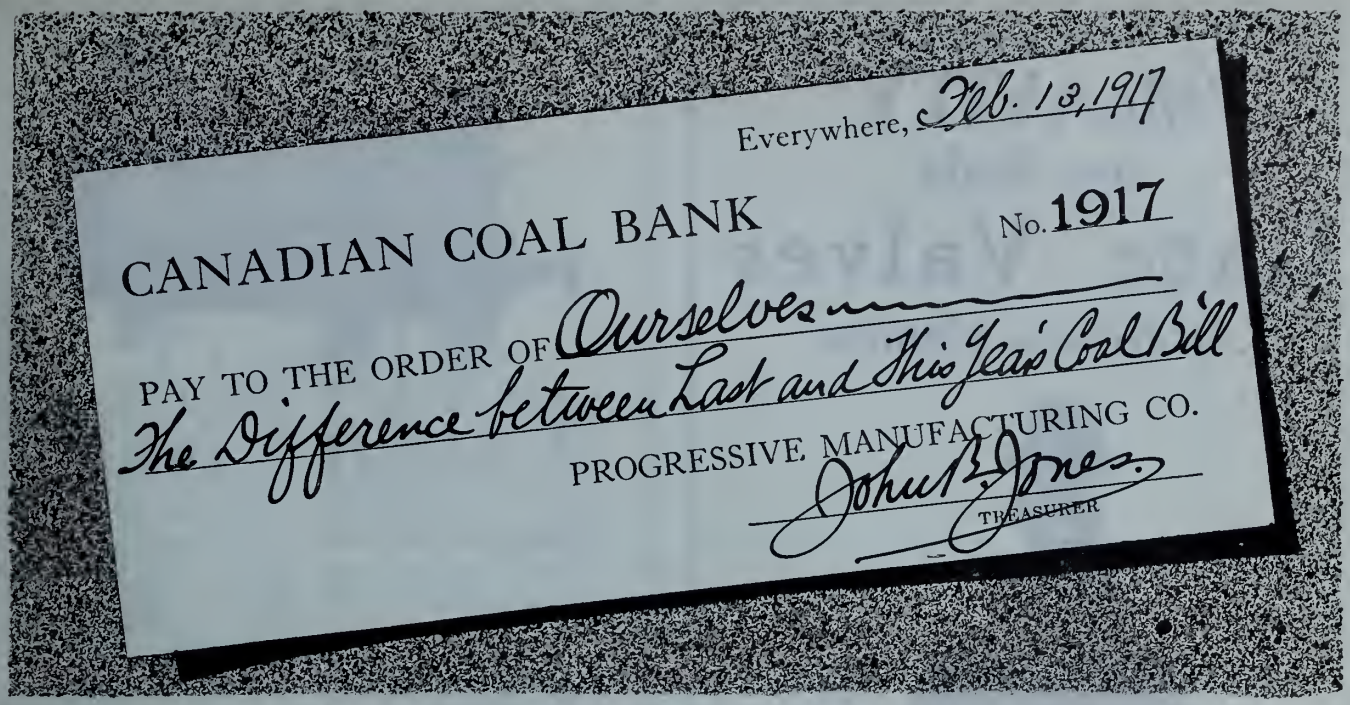
Accidents due to high and low water are occurring continually. Your plant may never suffer, but have you assurance that it won't? Have you taken the necessary precautions against this danger?

The Vigilant Feed Water Regulator is guaranteed to keep water level within ¼" of middle gauge. It is a positive prevention of dangers arising from high or low water.

Investigate it to-day!

The Chaplin-Fulton Manufacturing Company

28 Penn Avenue - - Pittsburgh, Pa.



Why Don't You Pay the Increase in Your Coal Bill to Yourself?

Last year, a certain plant, operating 5 boilers to capacity, paid $3.20 per ton for coal. Consumption averaged 15 tons per day.

Then their coal contract expired, the shortage came on and the price jumped to $4.20 per ton—just 31%. This meant an annual increase of $5475 in their coal bill! Naturally, this was a serious matter and the management, as well as the engineer, set themselves to work to reduce the heavy increase in cost.

Realizing that scale is one of the most prolific sources of fuel waste in the boiler room, the engineer suggested that a Dean Boiler Tube Cleaner be procured and the tubes thoroughly cleaned. The order was placed at once and the Dean installed.

Dean

Reg. U. S. Pat. Off.

Nearly 4000 lbs. of scale were removed from the five boilers! When cleaning was completed it was found that all the power required could be easily developed with four boilers (instead of the five previously required)!

The cutting out of one boiler reduced coal consumption 20%—lowering the increase in cost to 5%. Further experiments in flue gas analysis and a more careful system of firing resulted in a 10% additional saving.

To-day, this plant, despite an increase in coal cost of 31%, is paying 6% less for coal than it did last year!

Let the Dean show you how to do it

If your coal costs are going up, the Dean Cleaner will help you reduce them. The Dean cleans boiler tubes more thoroughly than any other method or device.. Consequently, Dean-cleaned boilers steam better and consume less fuel.

The Dean is ready to show you how it will cut your coal costs. You may try it without expense or obligation to purchase. Just tell us the size of your tubes, type of boilers, and where to ship. If the Dean doesn't make good, ship it back and we lose.

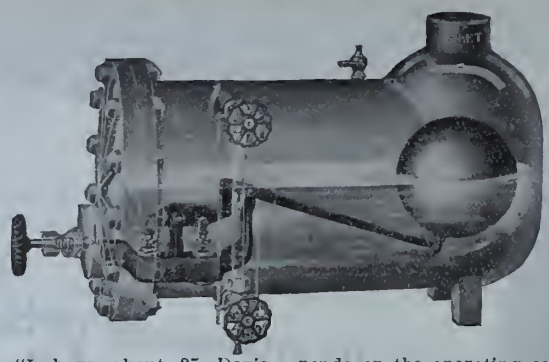
Montreal **Winnipeg**



"I have about 25 Davis Traps of various sizes in service, the majority of them for 22 years. I will gladly recommend them at all times," wrote H. F. Hustedt, Chief Engineer, Tulane University, New Orleans, when ordering his first repairs.

Possibly all Davis Traps would not last that long without repairs. Much depends on the operating conditions. On some installations they last longer than on others. But all Davis Traps have Tobin Bronze seats and valves—a hard, tough metal from which long service may be expected.

And when these vital parts of the trap do wear out, they may be easily renewed at slight expense.

We make Pressure Regulators . Balanced Valve . Float Valve . Steam Trap . Back Pressure Valve . Exhaust Relief Valves . Stop and Check Valves . Pump Governors . Damper Regulators . Radiator Air Valves . Emergency Stop Valves.

You are Paying Too Much for Coal

THE COE Turbine Undergrate Draft Blower will cut your coal bills, because it will enable you to burn the CHEAPEST grades of fuel, efficiently, economically and well.

The COE Turbine Blower

is cheaper and better than a Central Plant; cheaper because it costs less to install and keep up, better because each boiler is equipped with its individual blower.

The COE Blower will greatly increase your boiler capacity, produce complete combustion, and eliminate smoke. And because your draft is mechanically made you are independent of the changes in the wind or weather.

AUTOMATICALLY CONTROLLED. Once regulated it is set for good. Responds quickly to demands. No peak too great to meet. Will not harm the boiler. Endorsed by prominent engineers, and used by many large power plants. Easily installed.

YOU NEED IT. Write for prices and our special proposition.

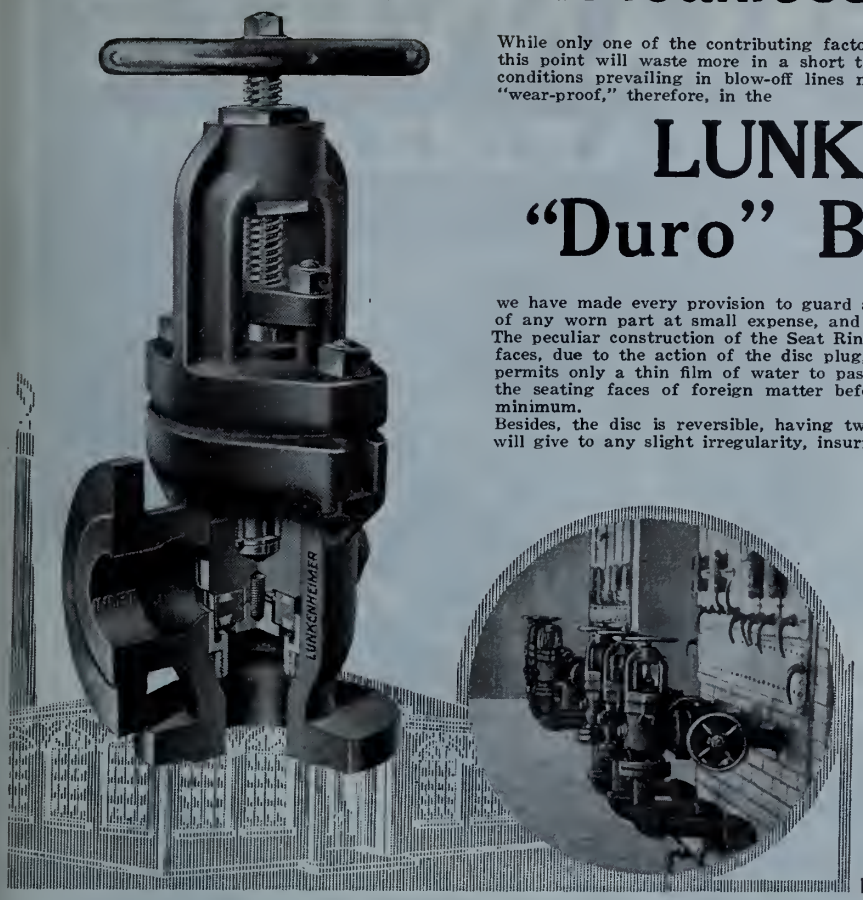
A leakless blow-off---



While only one of the contributing factors in boiler economy, is of vital importance—a small leak at this point will waste more in a short time than the cost of a good valve. The extremely severe conditions prevailing in blow-off lines make it impossible to construct a valve that is absolutely "wear-proof," therefore, in the

LUNKENHEIMER "Duro" Blow-off Valve

we have made every provision to guard against and reduce wear, and to permit the repair or renewal of any worn part at small expense, and without loss of time.

The peculiar construction of the Seat Ring and Disc in the "Duro" provides self-cleansing seating surfaces, due to the action of the disc plug, which cuts off the inlet when the valve is being closed and permits only a thin film of water to pass between it and the cylinder of the seat to thoroughly cleanse the seating faces of foreign matter before the disc is brought home, thereby reducing wear to a minimum.

Besides, the disc is reversible, having two alloy faces which, being softer than the seat ring material, will give to any slight irregularity, insuring a tight valve at all times.

Stem and bearings are bronze, and all parts, including the reversible disc and the seat ring, can easily be renewed.

The materials used and the workmanship are of that high order which characterizes all Lunkenheimer Products.

Specify Lunkenheimer "Duro" and insist on getting the genuine.

Your local dealer can furnish them; if not, write us.

JOHNS-MANVILLE
PACKING STANDARDIZATION

Sifting a thousand packings to give you the best

IF EVERY screw-thread had a different pitch, and for each thread you bought nuts of varying styles, because each was strongly recommended—repair jobs would last a lifetime, and emergency stocks would reach huge proportions.

Yet this is virtually the packing situation — or was, until Johns-Manville undertook Packing Standardization. Fifty-seven brands for each stuffing-box—annual fashions; heavy expense incidental to the manufacturer of varieties, and most of this expense passed on to consumers; economic waste, fighting brands, and, as a whole, inadequate solutions of packing problems.

So we decided to standardize our packings, and were prepared for initial loss of business. But as a matter of fact our business jumped. Engineers found that instead of repacking three times a season, a set of Sea Rings lasted two or three years—and they found new places all around the plant for this long-serving power-saver. So with Universal, with Service Sheet—with all the J-M Line.

By designing, not for selling novelty but for service, we've simplified your buying—and in so doing have improved each individual packing and advanced packing science. We've taken packings out of the bulk material class and put them on a straight engineering basis.

Fewer packings, and *better* packings—that's the achievement of Johns-Manville Packing Standardization.

COAL FAMINE

You owe it to the Empire that you get the utmost out of your Steam Plant. Your competitors have found that the use of our Boiler Preservatives, Protecto and Protectocoat, for interior and exterior use on your Boilers, are essential to get same along with *Plibrico One-Piece Lining* and *Plibrico High Temperature Bond for repairs*. These materials are revolutionizing Boiler Room Costs.

PROTECTO
BOILER PRESERVATIVE

Is not a water treatment but has an affinity for hot metal. After clearing your Boiler Plates and Tubes of Scale it forms a protective enamel to which further scale will not adhere. We are willing to give you thirty days' free trial and ABSOLUTELY GUARANTEE PURE STEAM. Prevents foaming or priming.

PROTECTOCOAT
FOR COATING YOUR BOILER BRICKWORK

Fills up present cracks and prevents new ones forming. Will last FOUR YEARS. Cold air penetrates all untreated brickwork and thereby reduces percentage of Carbon Dioxide in your chimney gases from the practical Maximum percentage of 14% to perhaps as low as 3%, entailing a loss per $1000 fuel of $15.00 to $535.

Do you know that 1/16th inch Scale on inside of Boiler Shell will waste 13% of Fuel?

ELECTRIC PLANTS. We represent a maker of everything in Vulcanized Fibre products.

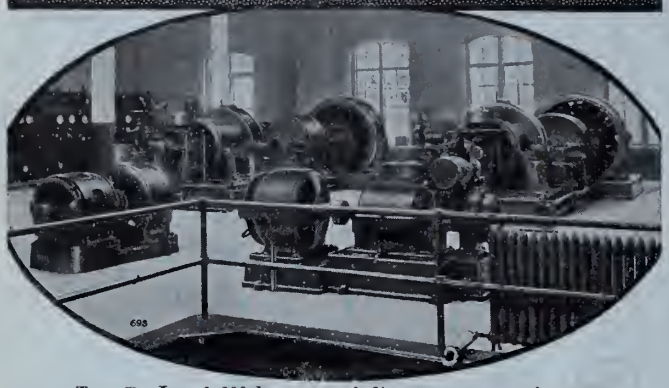
DE LAVAL
Geared Direct Current Turbo Generators



Two De Laval 600-kw. geared direct-current turbo generators installed for the Pacific Mills, Lawrence, Mass., high pressure condensing service, supplying power to variable speed print machines.

Flexible, Accurate Speed Control and Maximum Output Made Possible by De Laval Geared Direct-Current Turbo Generators

When alternating current distribution, speed variation for individual machines is difficult. With direct-current, on the other hand, each machine can be studied separately and speeded up to the maximum, thereby increasing the output.

The gain thus obtained over fixed speed throughout may amount to 5 or 15%.

A direct-current generator geared to a steam turbine is superior to transformers and rotary converters, as it is more efficient, costs less, occupies less space and involves less complication.

The installation shown has given reliable and efficient service since it was put in service over three years ago.

The use of the gear permits the steam turbine to run at the best speed for efficiency and simplicity. The turbine can be adapted to any steam conditions, as high pressure condensing, exhausting against back pressure, exhausting partly to condenser and partly to manufacturing processes, or utilizing the exhaust of reciprocating units.

All De Laval Machines are distinguished by moderate peripheral speeds, large running clearances, horizontally split casings, close speed control, interchangeability of parts, due to manufacture on the limit-gage basis, and the fact that each machine is guaranteed as to efficiency and is fully tested at the builders' works.

Ask for Catalog No. 48 and state conditions of use so that detailed information can be sent.

Sales Offices in all Centres *Representatives Everywhere*

WHEN a certain manufacturer bought his belts, the salesman told him to "run them at just the right tension."

So once a month every belt was tested, and if not tight enough it was taken up, this work being done on Sundays and holidays, at "time-and-a-half."

But this made his friction load high. Bearings required too much oil, and when his belts slipped, men and machines had to stand idle until they were taken up. So finally they used belt dressings, rosin, soap or "a little castor oil" to stop the slipping, and now his belts give him more constant trouble than anything else in the plant.

* * * * * *

There is another man in his town whose belts are old. He hasn't tried the tension for many years, because there isn't any tension. They run easy or slack, and when called upon for extra duty they respond cheerfully.

For this man has long since learned the CLING-SURFACE way. His belts never slip, even when running heavy, and the friction load is very small. About once a month or oftener, depending upon how long the belt has been treated, one of his men takes a stick with a rag wrapped around one end, and dipping it in the CLING-SURFACE he places it against the face of a belt, passing it across until a very light stain appears on the pulley faces. Then he stops: that belt is trouble-proof.

Simple, isn't it? Yet the greenest workman can apply the new semi-liquid "easy-to-use" CLING-SURFACE safely, economically and correctly.

Instead of tying up the shop with "belt trouble," wearing out men and equipment, and having overtime charges to meet, **ONE MAN**, with a bucket of **CLING-SURFACE**, treats the belts. Oil, coal and time is saved, more power is delivered, and the drives become cheerful workers instead of disagreeable kickers in your factory.

Let us prescribe for YOUR drives; our service is free, **CLING-SURFACE** is guaranteed, and we have a plan 10,000 firms have found successful.

Remember, use CLING-SURFACE and you won't need belt dressings.

MARTELL PACKINGS MEAN MORE POWER

Ask "the man who knows" in any power plant what he thinks of the Martell Packings. We will leave it to his verdict. Power House experts know the worth of these packings by their good name or by actual experience with them.

Failure is out of the question with these packings.

Cut at a tangent to piston rod, and joints on diametrically opposite sides of piston are parallel. This arrangement of the joints of the ring allows the parts to adjust themselves to slight inequality of wear in the diameter of the rod, as they float freely. Therein lies superiority of Martell packings. WHY NOT GIVE THEM A TRIAL?

CANADA'S DEPARTMENTAL HOUSE FOR MECHANICAL GOODS

14-in. Graton & Knight Quarter-turn Drive in the Donovan Lumber Co., Aberdeen Wash.

GRATON & KNIGHT
Standardized Series
LEATHER BELTING

Tanned by us for belting use

Graton & Knight Bigness insures Graton & Knight uniformity

Graton & Knight Leather Beltings are uniform—

Because Graton & Knight are the largest belt makers, because they purchase and tan 285,000 hides a year, because their brands are selected and graded to the highest degree of uniformity from this enormous supply of raw material.

Uniformity is the most important factor in belting quality. A belt, like a chain, is no better than its poorest piece.

* * *

Only a big firm like Graton & Knight could establisb and maintain an equal degree of uniformity in its belting.
And Graton & Knight are the largest leatber belt makers in America.
This minute control of uniformity is possible only because of their large supply of leatber tanned by tbem for belting use. A smaller supply would prove a constant temptation to put dissimilar pieces of leather into the same belt.
Graton & Knight bides are tanned in the Graton & Knigbt tannery, especially for belting purposes, by processes perfected in 53 years of belting tannage. It would be impossible for them to maintain equal uniformity if they used several different tannages.
Finally, Graton & Knight in the manufacture of tbeir by-products use bellies, shoulders, and otber parts of hides not suited for belting—tbere is no temptation to include these in Graton & Knight Belting.

* * *

Tbis is wby Graton & Knight can make a complete and standardized series of leatber belting; and maintain so high and so fixed a degree of uniformity in eacb brand.
It is wby Graton & Knight First Quality **means** first quality—absolutely free from any mixture of seconds, shoulders or worse.

This is no time to experiment

with untried belting. High-speed production and continuous operation demand the *known* quality, the *proved* strength and ruggedness which have been built into Graton & Knight Leather Beltings for three generations.

The Graton & Knight Book on Belting is authority on modern belting practice. Write for a copy to-day.

Ball Bearing Hangers
—For Every Plant Everywhere

SPEED says the engineer! *Production* says the superintendent! *Profits* say the stockholders!

Boiled down, this means an economical power saving use of transmissions.

That's why such progressive firms as the Jones & Lamson Co., Springfield, Vt., make sure of the best equipment money can buy. That's why SKF Ball Bearing Hangers are to be found in this plant and every plant where repairs and replacements are reduced to a minimum.

SKF Hangers are self-aligning. They save power — lubrication — maintenance — equipment — shop attendance. They have no unnecessary weight or bulk—no complicated mechanisms. They stand the gaff of constant use.

If you have a hanger problem confide it to SKF experts—they'll solve it!

III IMPORTANT THINGS

TO CONSIDER ABOUT A SEPARATOR.

I. THE PLAN—Is it sensible, will it work, no matter how large the Separator or how well made?

II. THE SIZE—Is it big enough regardless of plan, will it hold a good dose of water?

III. THE CONSTRUCTION—Is it strong enough, are flanges heavy, how will it look by the side of a nicely finished engine? Send for catalog and note these points in

FOR CEMENT PLANTS

THE NATIONAL PORTLAND CEMENT COMPANY, LTD.

Durham, Ont., 9/20/16.

Magnolia Metal Company,
Montreal, Que.

Dear Sirs:

We have had excellent satisfaction from Magnolia Metal during the time we have used it, which has been some three or four years.

In our plant it is very important that there should be used the very best quality of babbitting metal as cement dust is something that grinds out the bearings very fast and therefore only the very best quality of metal can be used. We may state that we have used this metal in our kiln building, also where intense heat is generated and also in our grinding department, where the dust is liable to use the bearings up very quickly. We have also used it on our high speed engines in our Power House, and in all these various tests it has given extremely good satisfaction, so much so, that we do not care to use anything else that has yet come to our notice.

Trusting that your business will continue a success, we are,

Yours truly,

For Small Powers or Large Powers

Morse Silent Chains

Deliver the Goods

YOU will admit that loss of power means loss of production. You know that belts slip and lose power. Any mechanic will tell you that gearing becomes less efficient as the tooth wear increases.

Therefore speeding up present productive equipment is simply a question of using that transmission system which CANNOT slip and lose power, and DOES NOT decrease in efficiency as it ages.

Silent chains as a class combine all of the advantages of belting and gearing without their disadvantages. MORSE Chains are best, yes BEST, in the silent class because their exclusive "Rocker-Joint" operates on a "rolling" friction principle, while all other chain joints operate on a "sliding" friction principle.

Take any two objects handy. Roll one and slide the other over your desk and you will *see* why MORSE Chains last longest and are most economical.

The coupon opposite is a convenient invention for your consideration of this subject.

BOILER INSPECTION

The Steam Boiler Act, Chapter 252 R.S.O., 1914, With Amendments Chapter 58—6, George V.

STEAM BOILERS.

All Steam boilers constructed for use in Ontario must be built from designs which have been approved and allotted a registration number by the Steam Boiler Branch.

Used boilers, boilers sold or exchanged, and unregistered boilers brought into the Province must be inspected prior to being put into operation.

Notice of repairs to steam boilers, stating the nature and extent of same, must be sent to the Steam Boiler Branch, and should such repairs be considered extensive by the Chief Boiler Inspector, the boilers will require to be inspected

In each and every case the inspections must be made by Inspectors authorized to inspect boilers under the Steam Boilers Act, who are employed only by the Steam Boiler Branch of the Department of Public Works. Official certificates with the maximum working pressure stated thereon are issued to the owners of the boilers so inspected.

STEAM PIPING.

Drawings and Specifications of all high pressure steam piping must be approved and registered by the Steam Boiler Branch before any work of installation is commenced. The drawings submitted should show clearly the dimensions and layout of the main steam lines. Full particulars should be given as to the material used in the construction of the piping, and all valves and other fittings used in connection therewith must be of approved make.

Any deviation from the above requirements shall be deemed a violation of the Steam Boilers Act.

All communications in this respect should be addressed to the Steam Boiler Branch, Department of Public Works, Parliament Buildings, Toronto.

HON. F. G MACDIARMID, Minister of Public Works and Highways.
W. A. RIDDELL, M.A. Ph.D., Supt. Trades & Labour Branch

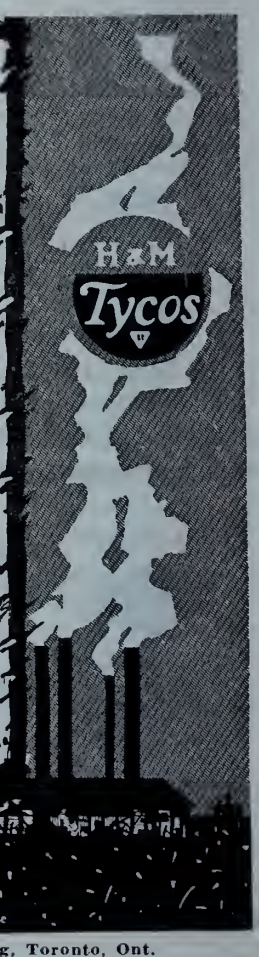
Tycos
Temperature Instruments

To meet the requirements of those innumerable processes requiring exact *indication, measurement and recording* of temperature, we have developed the most practical and reliable instruments that can be found.

H&M Type Angle and Straight Stem Thermometers
***Tycos* Recording and Indicating Thermometers**
Automatic Temperature and Pressure Regulators
Mercury Vacuum and Absolute Pressure Gauges
Engraved Stem Thermometers
Hygrometers, Hydrometers
Thermo-Electric and Radiation Pyrometers

In TYCOS Instruments you will find just the character of service you demand. Your requirements can hardly present unfamiliar angles to us, and we will be pleased to correspond along specific lines.



H&M Division
Taylor Instrument Companies
Rochester, N.Y.
There's a *Tycos* or *Taylor* Thermometer for Every Purpose

NO. 115 **201 Royal Bank Building, Toronto, Ont.**

Mention this paper when writing advertisers. It will identify the proposition about which you require information.

THE POWER HOUSE BUYERS' DIRECTORY

If what you want is not listed here write us, and we will tell you where to get it. Let us suggest that you consult also the advertisers' index facing the inside back cover, after having secured advertisers' names from this directory. The information you desire may be found in the advertising pages. This department is maintained for the benefit and convenience of our readers. The insertion of our advertisers' names under proper headings is gladly undertaken, but does not become part of an advertising contract.

UEHLING WASTE METER

COMBINED

CO_2 AND TEMPERATURE RECORDER

Record of CO_2 and stack temperature on one chart.

Does your fireman know how much fuel he is wasting? Do you know?

The **Uehling CO_2 Recorder** makes a complete 24 hr. record of your combustion efficiency and the **CO_2 indicator at the Boiler Front** holds the fireman responsible.

Get more **Steam** per pound of **Coal** and reduce your annual fuel consumption.

Let us know the number and size of your boilers and coal consumed per year, upon receipt of which information we will be glad to send you full particulars.

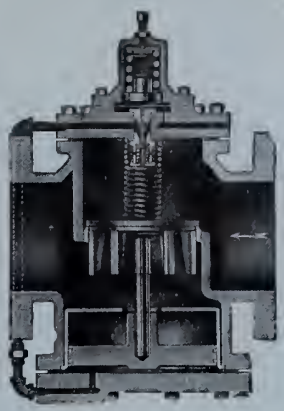
CO_2 Indicator for Boiler Front

Let us hear from you. We are pioneers in the manufacture of Indicators and Recorders for Power Plant purposes.

Send for our Bulletin No. 110.

Uehling Instrument Company

2008 Empire Building **New York City**



"NATIONAL"

THERE IS A

Kieley & Mueller

REGULATING VALVE FOR EVERY SERVICE

The valve above illustrated is specially designed for marine and power plant work, where positive and perfect control are essential

Lyman Metallic Packing

Has NO Weak Point!

Guaranteed for One Year

—Often Lasts Five!

In Lyman Metallic Packing the outside, stationary contact is made by rings of special. heat-resisting rubber composition—the inside contact on the moving rod by double rings of anti-friction metal. The joints in the metal rings are staggered, making the packing steam-tight from the first—and they close up with wear and the tightening of the gland.

As only anti-friction metal touches the moving rod, friction is reduced to a minimum—there is no scoring of the rod—nothing to hold the moisture and rust the rod during periodical shut-downs—and no lubrication beyond that from the cylinder is required.

Aside from the blow-outs, delays and trouble it saves, Lyman Metallic Packing actually costs less per month of service than cheap fibrous packings. Made to fit any stuffing box.

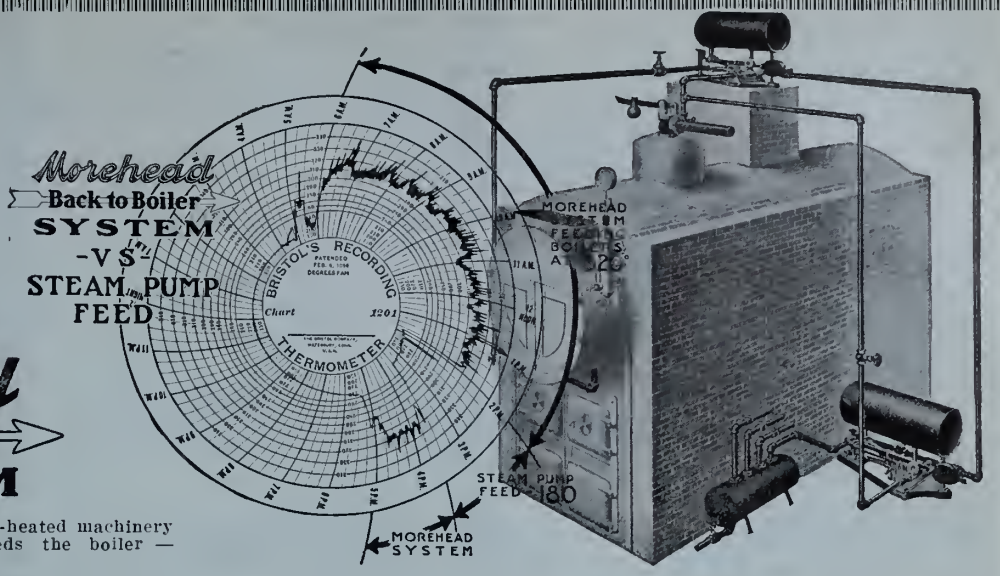
Replacing Steam Pumps

and individual traps with the Morehead Back-to-Boiler System is common practice. The

Morehead Back to Boiler SYSTEM

drains the heating lines and steam-heated machinery quickly and thoroughly and feeds the boiler — AUTOMATICALLY.



The pure hot condensation is returned to the boilers direct and under pressure—distilled feed water.

The life of your boilers is extended through the elimination of strains due to low temperature feed water from steam pump service. The purgative action of the pure, hot condensation removes and prevents the formation of scale on the tubes

The Northern Normal Industrial School of Aberdeen, South Dakota, substituted the Morehead System for their steam pumps, resulting in a 17% saving and the reduction in steam pressure from 15 pounds to 3 pounds on the heating system.

Write us fully about your steam troubles and receive valuable advice—no obligations. Ask for catalog.

★ The Above Temperature Record

shows on the same chart the relative temperatures of steam pump and Morehead System Boiler Feeds—taken under exactly the same conditions.

Between 2 and 2.30 P.M. the steam pump was cut into the line in place of the Morehead System.

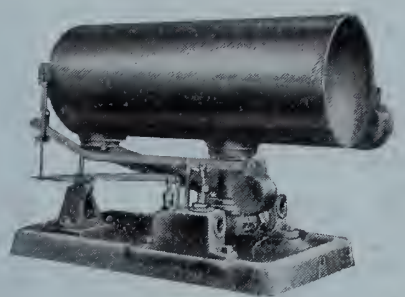
CANADA SALES CO., 183 Church Street, Toronto, Canada



Paid For Itself in Thirty Days

The chances are that if a device does not prove its worth in thirty days there is little chance that it ever will. But one of this

"Detroit" Systems for Handling Condensation

have records of **paying for themselves** in thirty days.

Not only will a "Detroit" System pay for itself in a short time, but will continue to save hundreds of dollars a year right in your boiler room by saving fuel.

In your boiler room, **as in many others**, there is no adequate provision made to return the condensation.

Better let us send you "Watch Your Condensation."

Don't buy that New Electrical Apparatus Just Yet

WE can supply you with high-grade apparatus that has been slightly used and discarded through no fault of its own, at an **immense saving in cost.** For instance, in many cases we take over entire plants simply because of changed conditions such as increased capacity, change of system, etc.

EVERYTHING IS OVERHAULED AND REFINISHED BY US AND **GUARANTEED** AS GOOD AS NEW, BOTH ELECTRICALLY AND MECHANICALLY.

Our catalogs of offerings should be in the hands of every power plant superintendent each time they are gotten out, and it will be worth while for anyone interested in this class of power plant equipment to be on our mailing list to receive all offerings.

Nearly all of the principal power, lighting and street railway plants in the United States are our customers.

WRITE FOR OUR LATEST CATALOG of **Power House Equipment, Street Cars, Motors, Hoists, Compressors, etc.**

MACGOVERN & COMPANY, Inc.

114 Liberty St., New York City

The Wrench of 25% Greater Efficiency

TRIMO PIPE WRENCH

Two new features have been recently added to the Trimo Pipe Wrench, namely Nut-Guards, in all sizes, and unbreakable steel frames, in leading sizes.

The Nut-Guards prevent the accidental rotation of the nut while in use.

These improvements add 25% to the usefulness of the tool.

The Trimo Pipe Wrench is made with wood handles in 4 sizes, 6-in., 8-in., 10-in., 14-in. and in steel handles in all sizes, 6-in. to 48-in. inclusive.

All Trimo Pipe Wrench parts are interchangeable.

The inserted jaw in the handle can be readily replaced when worn, thus adding to the life of the tool.

Nut with Nut-Guards

Inquiries from Importers and Dealers Solicited. Send for Catalogue No. 55.

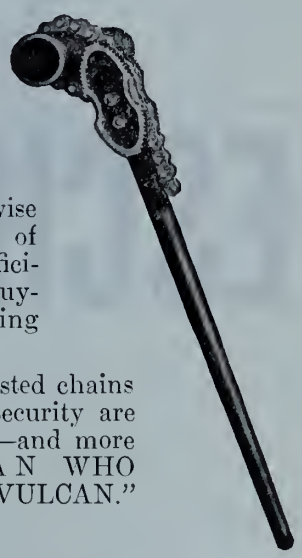
Vulcan-ize Pipe Work

7 sizes, accommodate ⅛" to 12" pipe and hold all records for service and the "Grand Prize" for excellence.



Only the penny wise begrudge the price of "VULCAN" sufficiency. Experienced buyers will take nothing else.

Double life, proof tested chains and knowledge of security are worth all they cost—and more —TO THE MAN WHO KNOWS THE "VULCAN."

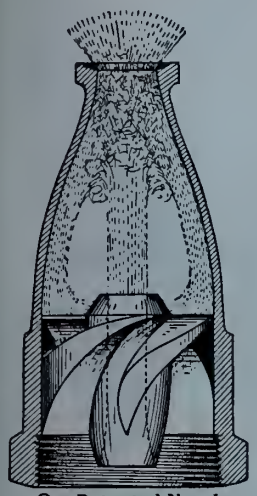
SPRACO COOLING SYSTEM

Costs Less to Install, Costs Less to Keep Up than Tower System

NOTE THIS FACT—operating power averages less than 1½% of power generated by engine—average cooling tower requires 3%



Our Patented Nozzle

An average vacuum the year round of 28 in. may be secured where the Spraco Cooling System is used.

It will pay you to instal the "Spraco." You soon get your money back. Costs little to instal and little to maintain and has a long life.

Requires Less Power for Operation Than Tower System

Installations on ground or roof. Ordinary roof will do, as there is very little weight involved. Systems installed to meet all requirements. Consult our Engineering Department—at your service to solve your problems. Write for catalog.

CURTIS Water Pressure Regulator

The Economy of this Curtis Water Pressure Regulator (See Illustration) lies in the fact that it greatly reduces the cost of keeping plumbing in order—This by obviating the wear and tear of water hammer or concussion in pipes.

This regulator is warranted to maintain the pressure desired, **with perfect uniformity, regardless of any fluctuations of outside pressure.** The workmanship and material of the Regulator **cannot be excelled.** Trouble from rust or clogging is **entirely avoided.** Delivery of water into service pipes at any desired pressure **is guaranteed.**

Send for special leaflet and price list to the manufacturers.

Inglis Boilers

FOR ANY SERVICE

Inglis quality has not been attained in a day or a month or a year or two. It represents the fruit of over half a century in meeting the requirements of boiler users.

Inglis boilers are Canadian standard in materials, workmanship and efficiency. They ensure a lifetime service with a minimum of repairs.

We are also sole Canadian makers of Erie City Water Tube Boilers, Vertical and Horizontal.

Our representatives will be pleased to show installations of our different types of boilers to prospective customers.

Write for prices and specifications.

MORRISON SAFETY VALVES

Beaver Safety Valve

An all bronze, double seat type safety valve for working pressures up to 200 lbs. per sq. in.

Model "C" Safety Valve

All bronze, single seat, side exhaust, working pressure up to 200 lbs. per sq. in.

Morrison Improved Safety Valve

Iron body, bronze mounted, for working pressures up to 250 lbs. per sq. in.

J. M. T. Safety Valve

Iron body, bronze mounted, for working pressures up to 200 lbs. per sq. in.

Morrison Twin Marine Safety Valve

Iron body, bronze mounted, for working pressures up to 300 lbs. per sq. in.

J. M T. Twin Safety Valve

Iron body, bronze mounted. Has inverted conical valve to prevent chattering on seat. Easing gear arranged to lift both valves simultaneously. This valve with its strength and compactness is a step far in advance of any other valve of this type manufactured.

MORRISON POP SAFETY VALVES

are strongly built, of best materials and are simple in construction. They have a full relieving capacity, are very sensitive in action and admit of being finely adjusted. We warrant them to be reliable, accurate and of the highest quality. All valves are provided with lock up attachments to guard against being tampered with.

All parts are renewable, and any worn or broken piece can readily be replaced.

Write us for full particulars of any valve.

If the valve you require is not here, we have others which will meet your requirements.

Lo-Press Safety Valve

Iron body, bronze mounted. For use on heating boilers carrying steam up to 15 lbs. per sq. inch pressure. The exhaust being on the bottom of the valve body forms a perfect drain, besides preventing flying matter entering the valve.

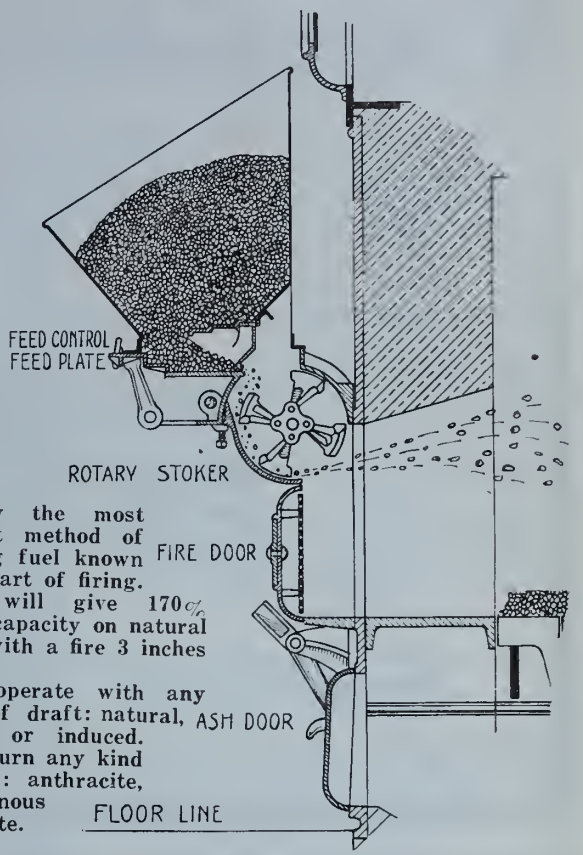
GALT SPRINKLER STOKERS

Two Type "A" Galt Sprinkler Stokers applied to 150 H.P. Return Tubular Boiler.
(Coal Hoppers immediately removable.)
Cost less than half of other stokers. Ask for prices.



Employ the most efficient method of burning fuel known to the art of firing.
They will give 170% boiler capacity on natural draft with a fire 3 inches thick.
They operate with any kind of draft: natural, forced or induced.
They burn any kind of fuel: anthracite, bitu m inous or lignite.

The Stoker mechanically feeds and perfectly spreads the fuel over the entire length and width of your present grates with the fire doors closed.

What Galt Stokers REALLY DO—

(1) Effect a saving in coal from 10% to 20%.
(2) Effect a saving in labor from 25% to 50%.
(3) Give a brilliant, thin, perfectly level fire.
(4) Give smokeless combustion.
(5) Increase the boiler capacity greatly.
(6) Increase the percentage of the CO_2.
(7) Burn the fuel completely to finest ash.
(8) Operate for years without need of repair. And other important points.

We supply Power-Turbo Blowers, McNaughton Rocking Grates, Damper Regulators and other Power Plant Equipment.
Ask for our illustrated catalogues on Stokers, Grate Bars, etc., etc.

PEILER'S SERVICE—

THE simple matter of buying goods at one price and selling at another never made a successful business. The ***Element of Service*** is what adds permanence to any organization, and the success of such organization is measured only by its ability to serve. The factor of ***SERVICE***—to the customer—always has been, and is, what has guided us in making connections with manufacturers of power plant specialties.

WE have had many years' experience solving difficult power plant questions, of all kinds and conditions, and the benefit of this experience is yours in dealing with us. If your conditions are not suitable for equipment supplied by us, we do not hesitate to advise what we think will overcome your difficulties.

ON this, and the opposite page, a few of our lines are shown. In our opinion, after long experience, with many tests and trials, they are the best, will stand up the longest, and give the most efficient service, of any that are made on the continent.

H. L. Peiler & Co.

Instruments for the Promotion of Efficiency and Economy in the Power Plant and other Manufacturing Departments

"Crescent" THERMOMETERS "Reform"

Power Plant Thermometers—for feed water, economizer, condenser, flue gases, etc., etc., are fully illustrated and described by Catalog Section No. 200. Our "Crescent" Thermometers are featured in a complete line, as are also our "Reform" Mercury Actuated Dial Thermometers which are now so universally used in Power Plants.

Catalog—W200.

GAUGES.

What more close friend of the Engineer than the Steam Gauge? And do you know that we were practically the first to manufacture the Steam Gauge in the world? And in all these years the S. & B. Steam Gauge has retained its reputation of superiority. Catalog—W1.

RECORDING GAUGES.

The Recording Gauge—its value in furnishing written records of pressure, vacuum or draft—is now universally recognized. What progressive Power Plant is without it? If yours is, let us send you catalog No. 100, which will tell you why you should have it—and why you should select the "Columbia."

Catalog—W100

RECORDING THERMOMETERS.

No need of explaining the absolute necessity of recording feed water, economizer, condenser, and flue gas temperatures. Our "Columbia" Recording Thermometer is acknowledged by many prominent Engineers to be "just superior all 'round," Mercury Actuated, Steel Construction. Day and Night Border Charts, Glass Interchangeable Pens, Easy Chart Changing, etc., etc., etc.

Catalog W300 tells all.

TACHOMETERS.

The function of the Tachometer is the measuring of speeds of shaftings, engines, machines, motors, etc., etc. No counting or timing necessary. Just a glance at the dial and you know the exact speed directly in R.P.M. Our line includes Haud Tachometers for portable use, as well as Indicating and Recording Tachometers for permanent attachment.

Pamphlet—W23.

Our Catalogs and Our Service

While our Catalogs will be found wonderfully instructive, we also maintain an Engineering Service Department whose services are at your command—gratis.

REDLINE DIFFERENTIAL DRAFT GAUGE.

A simple, inexpensive, yet invaluable instrumeut which should be on every boiler. It is an improved pattern of the inclined scale type draft gauge. Pamphlet—W75.

Our line also includes Counters, Engine Registers, Gauge Testers, Steam Calorimeters and innumerable other allied instruments. You should have our catalogs.

ALSO

Indicators
Gauge Testers
Calorimeters

COE TURBINE BLOWER

ONE of these Blowers under each of your boilers will give you pressures you never saw before. It will do it efficiently, economically, and receive the full approval of authorities.

The COE TURBINE BLOWER slashes coal bills. It enables you to burn cheap fuel with minimum smoke, high CO2 results, complete combustion. It will give you a flexible fire, always under your control, ever ready to respond to peak load demands. Your Recorder will write a story of better, steadier steam pressure the day you install this wonderful machine.

The COE TURBINE BLOWER is well made. The best material goes into its construction. It is built to stand up and give service week-in-and-week-out, and never require so much as a minute's attention. In fact, the best way to care for a COE TURBINE BLOWER is to LEAVE IT ALONE.

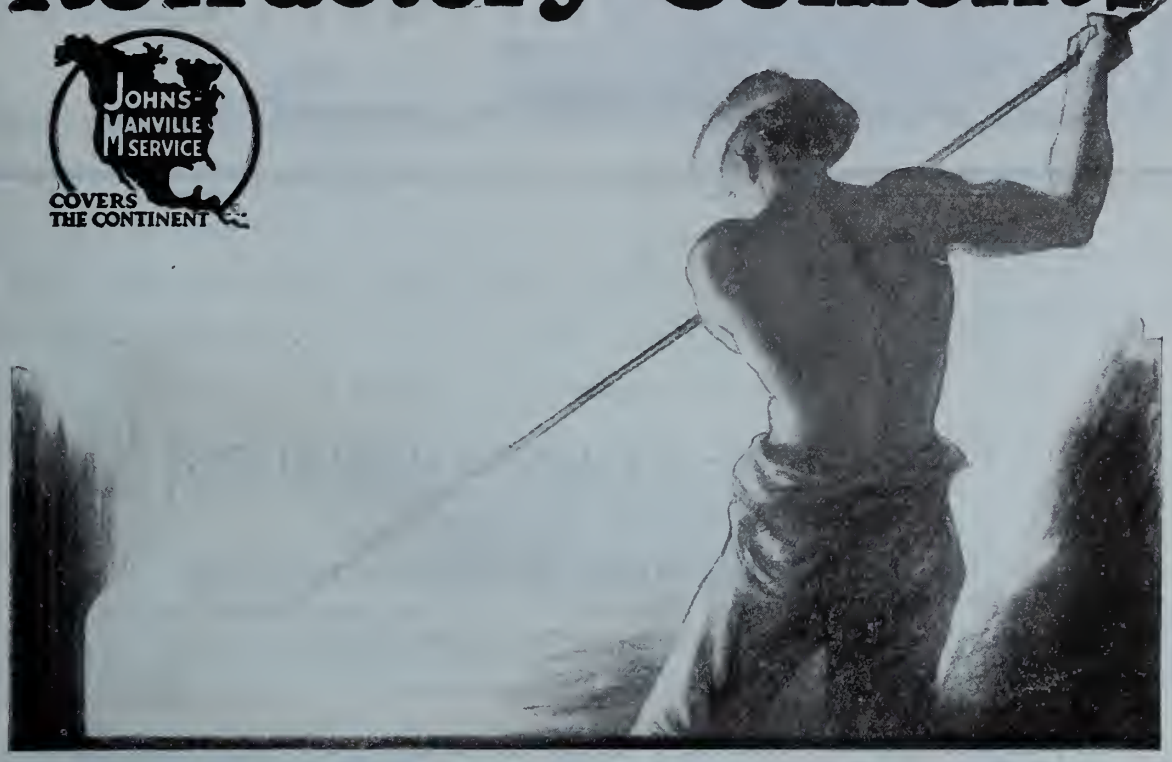
JOHNS-MANVILLE Refractory Cements

JOHNS-MANVILLE SERVICE COVERS THE CONTINENT



Fewer shut-downs—less upkeep expense—these are the "clinchers" for Johns-Manville Refractory Cements

Just as a chain is no stronger than its weakest link, so with all brickwork that is exposed to heat—its life in service depends on the individual brick joints.

The problem is not merely to secure a bond that will resist heat where ordinary fire-clay fails — although our Refractory Cements withstand temperatures up to 3100° F. without fusing or melting. The first essential—whether in a boiler-setting, a kiln, or a hot-blast stove—is a bonding material which will cushion the continual expansion and contraction of the brickwork as temperatures change.

Johns-Manville High Temperature Cements vitrify at low heats, gain strength as temperatures rise, and yet remain sufficiently elastic to withstand tension or compression without squeezing out at joints. Use No. 31 or No. 26 (depending on the temperature service) for the bond, then cover the whole interior face with a wash of No. 32, and you have a setting that will outlast the ordinary clay setting four or five times—a smoother wall, too, that offers slight anchorage for slag or clinkers.

We have issued a special leaflet on Johns-Manville High Temperature Cements which you will find interesting. It's yours for the asking.

Nonpareil Cork Covering after 15 years' service.—Strawbridge & Clothier, Philadelphia, Pa.

Fifteen Years on a Brine Line

In 1901 a brine line in the store of Strawbridge & Clothier was covered with Nonpareil Cork Covering. Fifteen years later, in 1916, the line was dismantled. It was found that the pipe had almost entirely rusted out from the brine inside, but the

Nonpareil Cork Covering For All Cold Pipes

was in practically as good condition as when first installed. Think of it! After fifteen years of hard service the covering had changed so little that a large part of it was used again for insulating another line.

Is the cold pipe covering in your plant showing equal durability? Probably not, unless it's Nonpareil Cork.

Full information, samples and prices on request.

MARSH and AMERICAN

Steam and Power Driven Pumps and Air Compressors

Marsh and American Pumps are especially adapted for long, hard service because they are *extra heavy* in design and of *extremely rigid construction.* Every unit is built amply strong to withstand 24-hour-a-day service and to stand up under any unforeseen strain which may be placed upon it. Piston rods on the steam pumps are extra large and made of solid bronze. The water ends are equipped with heavy cast bronze removable bushings.

This superior construction not only insures continuous and satisfactory operation, but practically *eliminates expensive shut-downs.* Marsh and American Pumps are the product of over 25 years' experience in the design and construction of high grade pumping machinery. Over 135,000 in actual service throughout the world.

The AMERICAN-MARSH LINE OF CENTRIFUGAL PUMPS is composed of both single and double suction types which are designed for heads up to 125 feet. They are equipped with wide ring oiled bearings and the single suction type has overhanging casing enabling the discharge to be taken at any angle desired.

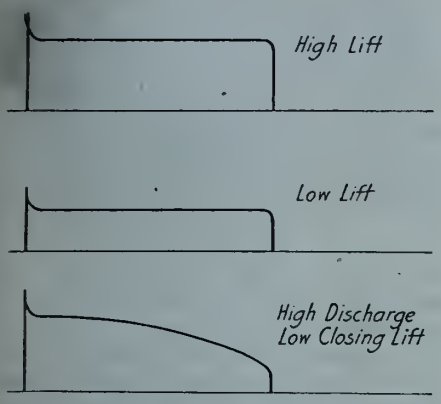
Development Towards New Type of Steam Safety Valves *

By George H. Clark **

The article presents in outline the theoretical considerations governing safety-valve action, and gives a record of experimental work done in the development of a new type of safety valve. In discussing the new type of valve here presented, actual diagrams of valve action have been introduced, together with results of capacity tests of sufficient duration to insure accuracy. An attempt is made to show that the efficiency of valves may be increased materially by using the proper design of seat, and that with two regulating rings instead of one as is usual, variations of advantageous character may be introduced into the valve action.

IN order to develop a safety valve of high discharge capacity at the greatest possible efficiency, and with the least possible weight of valve per pound of discharge, it is clear that, for any given diameter of valve seat, the one



FIGS. 1, 2, 3. DIAGRAMS OF LIFT CHARACTERISTICS.

giving the greatest lift will have the greatest discharge capacity if the seat angles are equal, and, with equal lifts and equal diameters, the flat seat (at right angles to perpendicular axis) is the most efficient. The flat seat was adopted at the start, due to its greater efficiency and to other considerations, to be mentioned later, and effort was directed toward methods of increasing the lifts, at the same time retaining all the advantageous factors obtaining in low-lift valves.

The two most serious objections to high-lift valves are the shock produced at closure and the tendency to lift water. There has been almost endless discussion over these points, resulting in more or less misunderstanding. The shock of closure depends on the height from which the disk drops to its seat and the velocity with which it is moving at the time it seats. By reducing the height from which the disk drops, the shock may be reduced so that the valve having an enormous lift after popping may close without shock if that lift decreases gradually with the receding pressure until it becomes small at the point of closure. This point has been very clearly brought to the experimenter, although no record is available, since the shock cannot be measured.

The second objection to high-lift valves, that of lifting water, is in reality less serious. It is useless for anyone to say that this objection is unfounded, because the tendency to lift water is almost entirely dependent upon the capacity of the valve, and the higher the lift the greater the capacity. It must, however, be remembered that every steam boiler has a certain required safety-valve capacity which is the same for all classes of valve, so that for proper relief the total capacity of the low-lift installation and the high-lift installation is one and the same. Now if the capacities are the same, the velocities in the boiler nozzles are the same, and one has no greater tendency than the other to lift water, since the rise in water level is due to velocity toward the nozzle. The two objections spoken of above may exist in high-lift valves, if, in the first case, the valve lacks the proper action, and in the second case if judgment is not used in the installation.

The results of shock are injury to the boiler and a short valve life, and if felt necessary this may be avoided, not by eliminating the high-lift valves, but by legislating against their bad feature, high closing lift. The lifting of water seldom occurs with stationary boilers, and it can be prevented by the proper choice of valve nozzle and of discharge capacity per valve. Fig. 1 shows the characteristic of certain high-lift valves which are objectionable, due to the high closing lift. Fig. 2 shows that of a low-lift valve in which the high closing lift has been obviated at the expense of discharge capacity. Fig. 3 shows the characteristic of an ideal valve having high capacity and low closing lift, and this was decided upon as the aim of the investigation.

Relation Between Discharge and Pressure Under Valve Disk.

In order to investigate the subject thoroughly, it is necessary to take into account two forces which produce valve action, not the least important of which

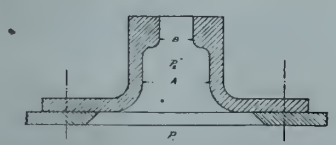


FIG. 4. REDUCTION IN AREA OF PASSAGE BETWEEN BOILER AND VALVE.

is the variation in pressure on the spring-load area of the disk—in other words, the pressure which exists below the disk in advance of and during the period of blowing. By means of certain assumptions we can apply the formula of flow proposed by Napier, and after the calculations are made they may be tempered by the actual conditions which exist, should they deviate from the assumptions.

Steam in the course of its passage

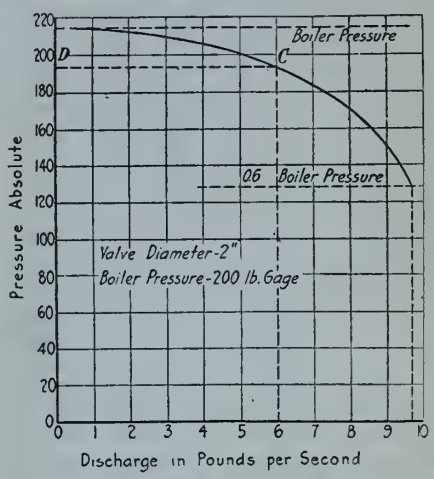

FIG. 5. RELATION BETWEEN PRESSURE UNDER DISK AND WEIGHT OF STEAM FLOWING.

from the boiler to the atmosphere encounters two reductions in area of passage which affect the pressure under the disk, one at entrance to the valve or the nozzle, and the other at the seat. The existent area conditions may be graphically represented by Fig. 4, in which the reduction of area from boiler to valve is denoted by the section at A, and over the seat by the section at B. The edges of the passage which form the approach to the section at A are rounded to a radius equal to the diameter of the passage, in order that the formula used may fit the case at hand. Let P_1 represent the boiler pressure, P_2 the pressure under the disk, and then assume that by some means the area at B can be changed as desired. When flow is established and conditions have become constant, the weight of steam passing the section B is the same as that passing the section A, and if the weight passing B is varied, that passing A goes through the same variation. Now the pressure P_2 depends on the weight flowing and the pressure P_1. Assign a constant value to P_1, say 200 lb. absolute, and by means of the following formula calculate the pressure P_2 with different weights flowing. So long as the discharge capacity at B is less than that at A, the formula

$$W = 0.029\ a\ \sqrt{P_2}\ (P_1 - P_2)$$

holds. When P_1 is assumed to be constant the formula may be written:

*From paper presented at annual meeting of American Society of Mechanical Engineers.

**Instructor in Mechanical Engineering, Massachusetts Institute of Technology.

$$P_2 = \frac{P_1}{2} + \text{or} - \sqrt{\frac{P_2}{2} - \frac{W}{(0.029\ a^2)}}$$

after the quadratic equation has been solved.

Assume now, for an actual case, that the diameter at A is 2 in., giving an area 3.1416 sq. in., and that P_1 is equal to 200 lb. absolute boiler pressure. Then calculate different values of P_2 with different weights flowing. These values of P_2 may be plotted against the weights, and the curve shown by Fig. 5 will result. This curve is interesting, since it represents quantities which may be arrived at by calculation only, and which must exist. Its significance is as follows:

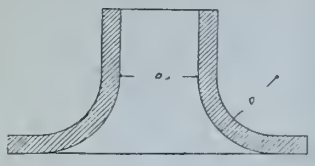

FIG. 6. STANDARD ORIFICE.

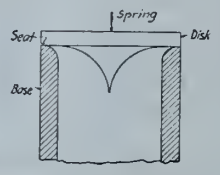

FIG. 7. VALVE INCORPORATING STANDARD ORIFICE EQUIVALENT.

With a safety valve of 2 in. nominal diameter and adapted to discharge a certain weight of steam, the pressure under its disk may be found from the curve in the following manner: Suppose its discharge is 6 lb. per sec.; then the points C and D are located and the pressure under the disk may be read. It is clear then from this curve that the pressure under the disk varies as the weight of flow varies; and that for valves of low lift the reduction of pressure is not great, but that for high lifts it increases rapidly. This curve is discontinuous when the pressure under the disk reaches a point where it is equal to 0.6 × boiler pressure, under which condition the area at B has become equal to that at A; the pressure P_2 is the minimum possible, and to all intents and purposes we have a standard orifice, so-called, the characteristics of which are shown by Fig. 6.

Our only assumptions up to the present are the neglect of friction and the rounded edges. It is clear that friction and square edges will tend to increase the drop in pressure, since both tend to reduce the discharge capacity of A, and it also follows that maximum capacity is not available with square edges at A. In other words, the full advantage of the hole in the boiler is not available unless this hole has rounded edges.

There results from the further consideration of the curve in Fig. 5 a simple explanation of why a safety-valve disk settles back after the first sudden pop. Since the reduction of pressure on the disk does not take place until the valve is open or until flow is established, the lifting force is, at opening, that due to full boiler pressure and, the instant flow is established, this is reduced and the disk must necessarily settle back to a position of equilibrium. The design of a valve must then incorporate means to provide lifting force outside the seat area, to make up for the reduction of upward force on the load area due to drop in pressure over and above that necessary to compress the spring.

In any safety valve there are three factors which affect the rate of flow over the seat, and which are characteristic of the seat itself. They are vertical lift, seat angle, and the contour of the passage which approaches the seat. The flat seat is adapted to open the largest area per unit of vertical lift, and hence should be employed, all other things being equal. Since the approach to a standard orifice makes the throat sectional area 100 per cent. efficient, the characteristics of such an orifice should be employed. Professor E. F. Miller, of the Massachusetts Institute of Technology, was first to round the edges of a safety valve in order to increase the efficiency of discharge per unit of lift, and in so doing took a long step in the direction of high safety-valve efficiency. The valve shown in Fig. 7, in which the standard orifice (or better, its practical equivalent), is incorporated, follows the theory proposed by him several years ago. The full benefit of the standard orifice would be available, regardless of the type of lip provided, if the passage area from the seat outward increased; but to produce a high-lift valve the maximum available pressure between the lips consistent with maximum discharge must be used.

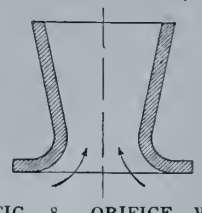

FIG. 8. ORIFICE WITH PRESSURE BEYOND THROAT VARYING INVERSELY AS AREA.

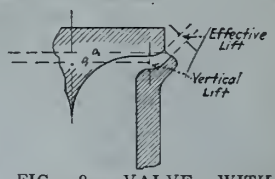

FIG. 9. VALVE WITH MAXIMUM PRESSURE BETWEEN LIPS.

Steam Flow as Affected by Shape of Orifice

A consideration of the pressure conditions within a standard orifice, of which Fig. 6 is an example, will give valuable information. In this type of orifice the area of each section beyond the throat section is equal to that at the throat section; and it has been found that at the throat section and at each section of equal area thereafter the pressure is very closely equal to 0.6 × boiler pressure, and that the back pressure into which this orifice discharges has no effect on either the weight discharged or the existent orifice pressures unless this back pressure exceeds 0.6 × boiler pressure. If it does exceed 0.6 × boiler pressure, the discharge capacity is reduced and the pressure throughout the orifice is increased. With the orifice of a shape shown in Fig. 8, but of equal throat-sectional area, the weight discharged is the same as before, but the pressure after the throat section varies inversely as the area.

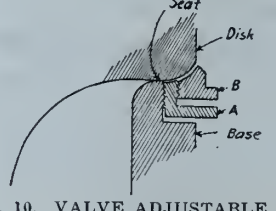

FIG. 10. VALVE ADJUSTABLE FOR VARIABLE LIFTING FORCE.

It follows from the above consideration that in order to produce maximum pressure between the lips there must exist at full lift an equality of area at each section outward from the throat of the orifice which is located at the seat. Since the effective disk diameters are constantly increasing, the effective lift must be reduced as the passage is lengthened. This can be done by giving the passage an upward slope, as shown by Fig. 9, which illustrates graphically the reduction of effective lift with increasing diameters such as D_1 and D_2, at which the vertical and effective lifts are measured.

If a valve of the above characteristics is constructed and blown, it will be found to have an extremely high lift, and the opening of such a valve is so sudden as to be truly explosive. A very large percentage of the pop lift is sustained if the popping pressure is held constant, and when such a valve starts to blow down, the lift gradually decreases during the blow-down period until a certain point is reached where the pressure becomes such that the valve disk drops suddenly to closure. This construction will produce a blow-down which is likely to be a third of the boiler pressure, and forces its designer to incorporate means of regulation which will give a small blow-down without interfering with the capacity or other features of valve action.

Regulation for Warning and Blow-down

The question of adjustment presents the real difficulty in safety-valve design. Means for regulation should in general perform their functions with as little effect as is possible on the lift and, per unit of lift, should produce no effect on the discharge capacity. Other than lift the two functions to be controlled by regulation of the variations in lifting force are warning and blow-down. A valve which chatters or vibrates at the instant of opening, or sizzles at that time, shows a lack of lifting force at low lifts, and one which shows an excessive blow-down demonstrates that the lifting force at low lifts is too great to allow of closure, and it follows that the requirements of warning and blow-down are somewhat combative. If possible the regulation of one should be made independent of the other. Blow-down is an absolute necessity on the spring-loaded type, due to the existence of lifting force outside

the spring chamber, and it is clear that attempts to reduce the blow-down will tend to decrease the lift and relieving capacity. In general, the real secret in the

FIG. 11. VALVE ARRANGED FOR TEST.

design of a perfect safety valve lies, not in the production of excessive lifting force, but in controlling and adjusting it; the action of a valve is dependent, not on the quantity of lifting force, but on variations of lifting force with discharge capacity and pressure.

Design of New Valve

Fig. 10 shows a valve having means for adjustment which are based on the production of variable lifting force as stated above. The two annular rings shown at A and B carry on their upper surfaces curves which approximate in shape the curve of the disk. The inner ring A, which I choose to call the warning ring, is threaded upon the base of the valve just outside the flat seat and carries, threaded upon it, the ring B, which is adapted to control the blow-down. These rings may be lowered away from the disk, or given what I choose to call initial clearance.

Now it is clear that if both of these rings are lowered an extreme distance, when the valve tends to open no lifting force will be available. If the ring A is raised to a position near the valve disk,

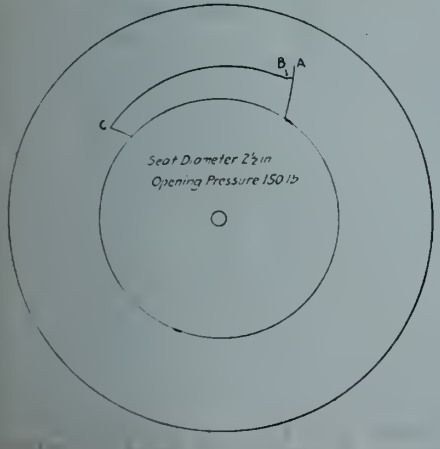

FIG. 12. PERFORMANCE CHART OF 2½ INS. EXPERIMENTAL VALVE.

a lifting force will be provided which will depend (1) on the pressure produced between it and the disk and (2) on the extent of the disk area on which this pressure acts. As was shown in the discussion of the standard orifice, the pressure depends on the area of the passage, and the area in the valve is a function of the initial clearance and the shape of the curve. These factors are built into the valve to produce the desired result, which is to provide lifting force at small lifts to overcome excessive warning; and it has been found that with the proper shape of ring, on its initial clearance depends the warning of the valve. Since this warning ring alone produces only small lifts, it has no appreciable effect on the blow-down.

Again, as the blow-down ring B is raised from its lowest position, there is a tendency to build up pressure between it and the disk when the valve is open, which tendency increases as the disk is approached. If a reasonably large clearance is left, it is clear that this ring produces almost no lifting force at low lift, since the area of the passage along this ring is large in comparison to that over the seat; and it follows also that, as the disk lifts, the effect of its initial clearance on the area of the passage becomes less and less as lifting continues. This can be illustrated by a simple calculation. Suppose that, measured at the extreme outside edge of this ring, the initial clearance is 0.03 in. and that the angle at this point is 45 deg.; then if the disk lifts 0.1 in. in a vertical direction, the height of the passage over the seat will be 0.1 in., and at the extreme edge the increase in passage height perpendicular to the curves will be 0.07 in., since with a 45-deg. angle the vertical lift is only seven-tenths effective—so that the total height of the passage is 0.1 in., the same as that over the seat. Suppose now that the lifting continues; the area at the edge of this ring gradually approaches that over the seat and can be made to become equal to it by proper design at any chosen lift. It is clear then that for all of the initial clearance of the rings, we have at full lift gotten back to the area conditions of a standard orifice.

Tests of this valve prove the value of this method of regulation, in that all the requirements of practice are afforded by it for all of the high lifts. Any one sufficiently interested can lay out a valve of this type, and he will find that if the characteristics of the spring to be used are known, he can calculate with reasonable accuracy the lifting force at any lift and also an approximate value of the total lift. In calculations of this nature the reduction of pressure on the spring-load area, as previously explained, must be taken into consideration.

Diagrams Showing Performance of Experimental Valves

I have with some difficulty succeeded in getting some diagrams from valves under service conditions which, I believe, show in detail the results of the methods of regulation which are employed. Fig. 11 shows the arrangements of the valves for testing. The tests from which the diagrams were secured were carried on at the power plant connected with the new buildings to be occupied by the Massachusetts Institute of Technology.

One of the regular 4-in. valves was removed and a Y-base substituted in its place; the regular 4-in. was then placed on one of the branches and on the other was placed a special by-passed gate valve and finally, on top of this, the valve on test was connected. Under the above conditions the valve on test was well above 3 ft. higher than the top of the drum. Those experienced in safety-valve action will realize that this height is apt to seriously affect the action of the ordinary valve. The recording apparatus used consisted of a clock motion adapted to turn a chart once in 15 minutes. Bearing on this chart was a pen rigidly connected to the spindle of the valve and adapted to leave a record thereon of lift with respect to time, the lifts being multiplied by a ratio of approximately four to one.

Fig. 12 shows a chart of the performance of a valve with a 2½-in. seat. This

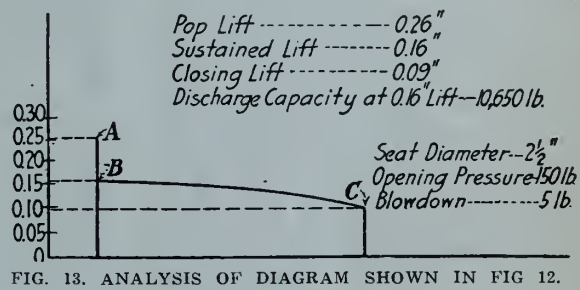

FIG. 13. ANALYSIS OF DIAGRAM SHOWN IN FIG 12.

valve was blown at 150 lbs. gauge boiler pressure and showed, under the existent regulation, 5 lbs. blow-down and almost no warning. In order that it may be clearly understood, it has been transferred to a diagram having rectilinear axes, on which is plotted the scale of lifts which resulted from the calibration of the recording lift gauge with an accurate micrometer. In Fig. 13 the sudden pop lift is shown at A, and the corresponding sustained lift at B. The variations in lift at the point B are further evidence of the readjustments of pressure which determine the pop and sustained lifts, an idea of which may be gained from the theoretical considerations previously stated in this paper. The discharge capacity of this valve was such that the popping pressure was not maintained, and the curve from B to C shows the reduction in lift, which in this type always corresponds to a reduction in boiler pressure. At C the valve closed suddenly, with less than half its initial sustained lift prevailing.

In other words, the drop lift of this valve, which is numerically 0.09 in., is about equal to that of a low-lift valve, while its discharge capacity at popping pressure is nearly twice as great as regards lift, and is even more when seat angle and efficiency are taken into ac-

count. This diagram shows the action of the valve when adjusted to give action somewhat similar to that to be found in some types of valves now procurable, and is in a good many ways ideal. Attention is called to the smoothness of the curve between B and C as evidence of

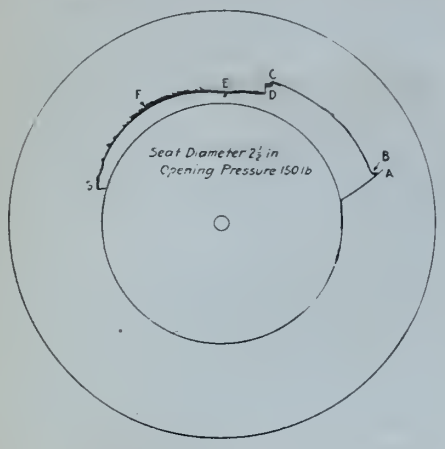

FIG. 14. PERFORMANCE CHART OF VALVE OF FIG. 12 WITH BLOW-DOWN RING LOWERED.

the Equilibrium between lift and boiler pressure existed as the boiler pressure existent as the boiler pressures is reduced.

Fig. 14 shows precisely the same valve with its outside or blow-down ring lowered slightly. This diagram, like the one preceding, is reproduced from a photograph of the actual diagram, and has not been transferred to rectilinear axes because of the difficulty in showing the fluctuations in lift. The section of the curve at A shows the pop and sustained lifts as before. From B to C is shown the gradual reduction of lift corresponding to decreasing boiler pressure, until the point C is reached, where the disk suddenly falls from a reasonably high lift to a much lower one. This action is due to the large initial clearance of the blow-down ring, which throws it out of action entirely when the lift valve at C is reached. The fluctuations in lift at the point C show the lack of equilibrium at this point in the action, which results finally in the drop to the lower lift. At the lower lift, represented by D, all the supporting force is that due to the inner or warning ring.

The downward slope of the curve from D to E shows the tendency of the valve to decrease its lift with decreasing pressure, and closure would doubtless have taken place at D, had not the fans been started at this point in an attempt to force the pressure back to the popping pressure. The section from E to F shows an increase in lift corresponding to the increase in pressure. The fluctuations in lift during this period show a tendency of the blow-down ring to come into action, it being prevented from doing so only by the lack of pressure. The fans were shut off without orders at F, and the valve immediately blew down and closed with 0.04 in. closing lift at G. If we suppose the diagram to have been completed by closure at D, as would have been the case without the high-lift valve with a closing lift less than that obtainable from any low lift valve or ordinary design. That this action can be and is continually repeated by valves of this type is a fact to which every one who has been a witness of the blowing of this valve will testify. To those who have heard such valves blow, no diagrams are necessary.

It was decided after the two preceding diagrams were secured to change to a smaller valve of lower discharge capacity, under which the pressure could be regulated as desired. It is my purpose to bring out by the three diagrams which follow the faculty this type of valve has to respond, under ordinary conditions of regulation, to accumulated pressure. above the opening pressure. The new Boiler Code rules, if put into force, will allow 6 per cent. accumulation of the pressure, and I wish to show by the diagrams what advantage may be taken of this accumulation.

Fig. 15 shows a chart taken from a 2-in. valve in which the pressure was not allowed to accumulate. The low closing lift in comparison to the sustained lift is to be noted. Fig. 16 shows the same valve with an accumulation of pressure over the opening pressure of 4 per cent. This is under the same regulation conditions as the next preceding chart. The substantial increase in lift and corresponding discharge capacity is to be noted, together with the same closing lift.

In Fig. 17, the valve was regulated to give a low sustained lift, and was then given the full 6 per cent. accumulation. It is clear that the lift at B is more than 10 per cent. greater than at A, so that the discharge capacity at 6 per cent. accumulation is more than 100 per cent. greater than that at the opening pressure. The low closing life is to be noted as before. The blow-down on this valve was about 2 lbs., so that this chart was made between a maximum

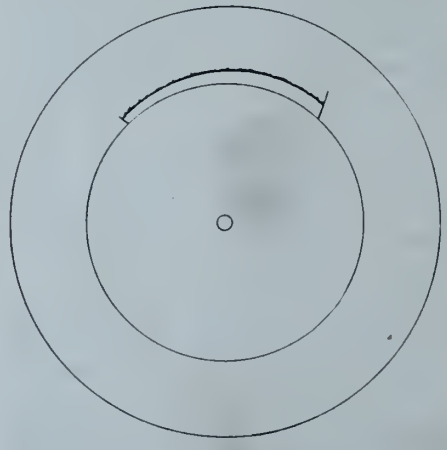

FIG. 15. PERFORMANCE CHART OF 2-INCH VALVE. SUSTAINED LIFT AND LOW CLOSING LIFT.

pressure of 159 lbs., and a minimum pressure of 148 lbs. The New Boiler Code specifications rate valves on their sustained lift at the popping pressure, and so it is clear that with this type the basis is amply safe.

In presenting the diagram shown in Fig. 18 for consideration, I believe I am bringing forward one of a safety valve which is absolutely new, both in conception and results. It has been the aim of safety valve designers to produce a valve which relieves a boiler with an

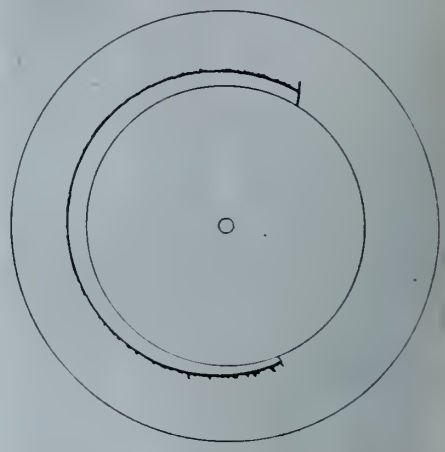

FIG. 16. PERFORMANCE CHART OF 2-INCH VALVE. PRESSURE ACCUMULATION BETWEEN OPENING AND CLOSING.

action that is smooth, while embodying as few sudden flucuations in pressure as is possible. The Boiler Code Committee recognized the exhibition of standard valves to respond to accumulated pressure by incorporating the 6 per cent. accumulation rule. The ideal safety valve for practical purposes is, I believe, one in which a reasonably low life is maintained at the popping pressure, but one which will on the slightest accumulation respond with an extremely high lift to take care of the emergency. If a low lift is available at the popping pressure for ordinary relief, a low blow-down may be incorporated, the condition imposed by absolute safety being that at slightly above the popping pressure the lift will have increased to such an extent that any possible emergency will be taken care of.

Fig. 18 shows a diagram from a valve which produces the above action, and is what may be called a second-opening valve. Many of this type have been built, and it has been found that with the proper regulation of rings, all valves having two rings will produce this action in modified forms. Imagine, first, one of the ordinary type blown with the outside ring removed. This would result in a low lift and a very low blow-down. Now suppose that the blow-down ring is in place, but that it is given such a large initial clearance that the valve will act, provided that it has sufficient capacity to relieve the boiler exactly as before, yet if it has not the required capacity the pressure will accumulate and the increase of lift resulting with only the inner ring in action will finally bring the outer ring into action, and a second pop will occur. This pop will result in a high lift, with corresponding high discharge capacity, and the valve size may be proportioned to give the required safety.

That this action can be accomplished in actual practice is shown by the diagram in Fig. 18, which resulted from the action of a 1¼-in. valve on a boiler,

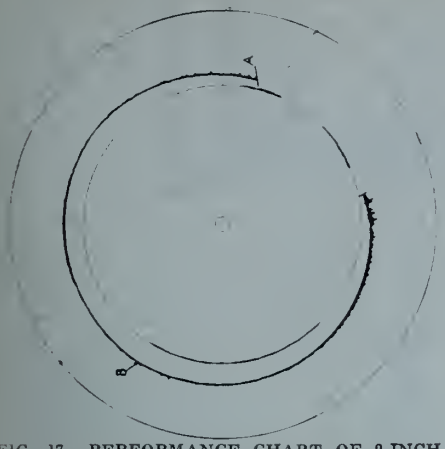

FIG. 17. PERFORMANCE CHART OF 2-INCH VALVE. LOW SUSTAINED LIFT WITH PRESSURE ACCUMULATION.

or rather boilers, of sufficient capacity to produce the required accumulation. The first pop and sustained lifts are shown at A, the sustained lift being very slow. The increase in lift between A and B finally results in the second pop, shown at B, which is the result of accumulated pressure. Between B and C the lift gradually falls as the pressure is reduced, until at C the outside ring goes out of action and the disk drops to a low lift, which is at the given pressure just sustainable by the inner ring. As the pressure is reduced the lift decreases, and after a slight blow-down the valve closes at D with a very low closing lift. This valve had a seat diameter of 1¼ in. and lifted at its highest sustained point about 0.11 in. This lift was the result of about 4 per cent. accumulation, and the calculated discharge capacity is 5,100 lb. per hour, which is approximately 170 boiler h.p.

Features of Design

Careful design will allow of bringing the second pop down very near the first one, and the limits of regulation may be so built into the valve by limiting the possible up and down movement of rings, so that this second pop will always come within a given range of pressure. This type of action has many advantages to recommend it. The absence of sudden excessive changes in relieving capacity and the low lift at closure are evident from the diagram. It is clear that if a boiler had two valves of this type, the second might be set to blow at a pressure corresponding to the point O on the diagram, so that the two valves would be able to handle the boiler at all ordinary times without the second pop, but in the case of emergency both would rise to the second pop lift. The installation would then be essentially a low-lift installation, but woud have all the advantages of high lift in the case of emergency.

Discharge Tests

In the course of the experimental work very few discharge-capacity tests could be run, since most available plants have no means of measuring the water used. Four tests were run at Annapolis, Md., at the United States Naval Experiment Station, which establish the fact that the standard orifice type is nearly 100 per cent. efficient in discharge capacity per unit of lift. The first three tests were made early in the experimental work, the fourth being run at a later date. The reported results of these tests are shown in Table I.

Test No, 2, when compared with the other tests. shows so low an efficiency that it obviously includes some error in the reported data, so it seems fair to assume that the efficiency is very nearly 100 per cent., or, in other words, within the limits of the experimental error in a test of this nature. As a comparison it may be of interest to note that the 3-in. valve assembled for test weighed only 8885 lb.

It is always interesting to compare the results obtained from any piece of apparatus with those which we know to be theoretically possible. In the case of safety valves the full-opening valve serves as a convenient basis of comparison, in that its capacities may be calculated without reference to the type of valve used. If we attach a standard orifice to a boiler we have then the most efficient way of discharging steam, and this on a basis of throat diameter may be characterized as the full-opening valve.

In line 1, Table II., are shown the capacities of full-opening valves of several diameters figured directly from Napier's formula. Line 2 shows the discharge capacity of valves of the same diameters as read from the table in the recent A. Soc. M. E. Boiler Code. I have assumed that these values represent standard conservative practice. Line 3 shows the discharge capacity of the type of valve which I have described, and is the result of calculations involv-

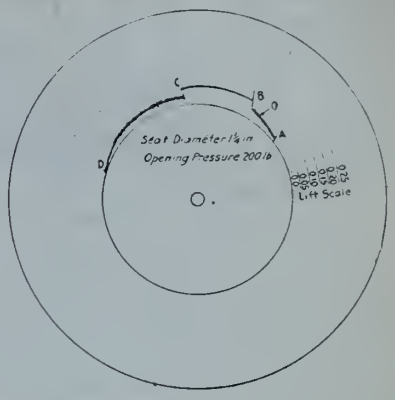

FIG. 18. PERFORMANCE CHART OF A SECOND OPENING VALVE.

ing the sustained lift as measured from the diagrams at the popping pressure.

It seems reasonable to believe that the spring load of a safety valve is to some extent a measure of the shock at closure, which may be expected. Since all valves of the same diameter have approximately the same spring load, some other basis than diameter must be chosen for comparison. Discharge capacity is the first requisite in all valves, and so the spring load has been calculated per 100 lb. of steam discharged per hour. Line 4 shows the spring load per 1,000 lb. discharge of ful-opening valves, which is, of course, constant. Lines 5 and 6 show the same quantity calculated for Am. Soc. M. E. valves and for the proposed type. Lines 7 and 8 show the percentage of full opening attained by the two available types.

There is reason to believe that we shall soon have boilers which will operate at 600 lb. pressure. Consideration of some of the values given in this table is interesting in this connection. A 4-in. valve set at 600 lb. pressure will have a spring load of approximately 7,540 lb., or about 3½ tons. Now if a 2-in. valve can be constructed to give twice the lift of the 4-in., it will have the same discharge capacity, but its spring load will be only one-quarter as great, or 1,885 lb. In other words, the discharge capacity varies as the first power of the diameter and the lift, but the spring load, which is independent of the lift, increases as the square of the diameter. It seems clear from this that high-pressure boilers will of necessity require small-diameter high-lift valves.

TABLE I.—RESULTS OF DISCHARGE TESTS ON VALVES OF THE NEW TYPE.

Test No.	Valve Diameter, In.	Opening Pressure, Lb. per Sq. In., Gage	Blowing Pressure, Lb. per Sq. In., Gage	Percentage Accumulation	Discharge, Lb. per Hour	Efficiency, Per Cent.	Lift, In.
1	2.5	150	158.8	5.86	17,325	99.43	0.252
2	2.5	200	212.9	6.44	16,892	78.88	0.238

7 Percentage of full opening attained by proposed type	26.6	25.6	25.7	.....	.....
8 Same for A.S.M.E.	9.51	8.67	9.05	8.50	8.15

Table II. shows the net result of the development in spring-loaded safety valves, and serves to emphasize the opportunities which may be grasped by the designer.

The question of the effect of back pressure in the casing of a safety valve has been much discussed. It has been said that it may operate in two ways to reduce the discharge capacity. First, the effective lifts may be reduced, and, it has been held that back pressure reduces the efficiency of discharge of the orifice. If any of the disk area is exposed to back pressure the lifts will be reduced to some extent, but consideration of the theory of flow through an orifice, and particularly a standard orifice, brings out the fact that as long as the back pressure in the casing is less than 0.6× boiler pressure, the discharge of the orifice is not affected.

The discharge-capacity tests made some years ago by P. G. Darling, mem. Am. Soc. M. E., went some distance in establishing this fact, although no general conclusions were drawn. It remained for a section of a Committee of the American Society of Refrigerating Engineers, with Prof. E. F. Miller, Mem. Am. Soc. M. E., as chairman, to establish this fact beyond question. In refrigeration installations long discharge pipes are required, and the pipe friction produces so much back pressure that either the ordinary type of valve is useless or its discharge pipe must be of an excessive size. Experimental work resulted in a valve which was so constructed as to take advantage of back pressure to increase its lift without in any way having its discharge

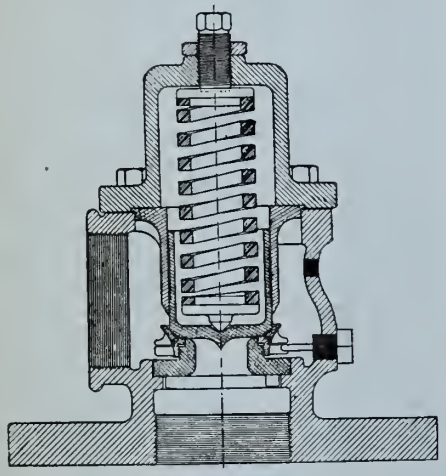

FIG. 19. STEAM SAFETY VALVE OF APPROVED DESIGN.

capacity per unit of lift reduced. That valve was due to the ingenuity of F. L. Fairbanks, Mem. Am. Soc. M. E., of the Quincy Market Cold Storage and Karehouse Co., and has been adopted as the standard in Massachusetts for refrigeration work. The possibility of working with back pressure operates to reduce the discharge pipes to reasonable sizes in spite of their length.

Examples of the New Valves

Fig. 19 shows a complete view of a valve which has the desired advantages. In the first place, valves of high lift, and by that I mean higher lift than any of those obtainable at present, must be guided from above, as guides in the base will cause too great a drop in pressure on the disk area. In this view the disk is made in the shape of a hollow piston, which is guided by a cylin-

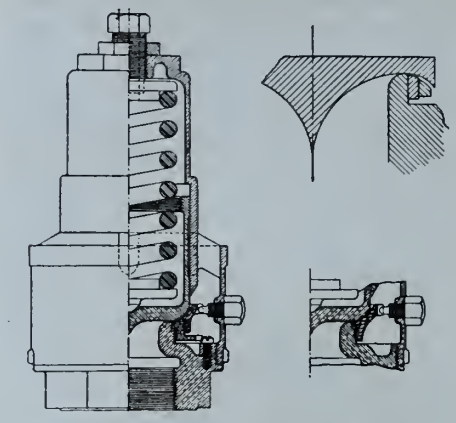

FIG. 20. LOCOMOTIVE VALVE OF APPROVED DESIGN.

drical sleeve that encloses the spring chamber. The fit existing between these is extremely loose, and no attempt is made to prevent leakage by the disk. This loose fit insures that the disk will not bind because of expansion or contraction between the members due to temperature changes, and is long enough in relation to the diameter of disk so that it will never cock. Its looseness alone insures that the disk will come to a uniform bearing on the seat, and it has been found that under no conditions of back pressure has the leakage by it been sufficient to produce pressure in the spring chamber, which is vented. With this type, the back pressure may be built up to nearly 0.6× boiler pressure without hampering the discharge capacity in the least, and since the back pressure is a result of the effective opening of the valve, it has no effect whatever on regulation if it is brought about by the means shown.

In the case of duplex or triplex valves having a common discharge pipe, the opening of one will tend to open the other, due to the exposed area outside the seat and the impossibility of back pressure acting downward on the disk. It must be understood that the commercial types of valves which are shown in the following illustrations are not dependent on back pressure for any part of their action, but are in every case adapted to work with it without harmful effect. Fig. 20 shows a locomotive valve of approved design, and Fig. 21 the proposed marine type of exceedingly large capacity.

Having shown a valve in which there is substantial increase in discharge capacity over those in use at present, and having demonstrated that this may be accomplished with lower closing lifts than are now the rule, attention is called to a possible improvement in this type. It will have been noted by this time that in all the types shown the passage turns upward from the seat region, and it is also clear that so far as the area conditions go it might as well be turned downward, the area conditions will remain constant, as illustrated in Fig. 22, but there will be available as lifting force a factor which would act upward on the disk, and which is commonly known as a jet action. Some few valves of this type have been constructed, and the results gained have been convincing of their possibilities. Enormous lifts have been attained with the same absence of shock at closure as is the case with valves herein described. The problem has been by no means solved, but advances have been made in a direction which tends to indicate that it will be solved finally, and will result in enormous discharge capacities per inch of valve diameter, with the same efficiency per unit of lift. It is clear from a consideration of the diagram that the force due to jet action will not be destroyed by back pressure, as the velocity of the issuing jet of steam is a function of the orifice pressure, which pressure is not affected by the back pressure.

In closing this paper, attention is directed to the fact that this valve is not essentially a high-lift valve. It may be designed to give low lifts as well as high lifts, and is easily adaptable to the proposed Am. Soc. M. E. specifications. It will, of course, under the specifications, benefit by reason of its flat seat and by a discharge capacity about 30 per cent. greater than the 45-deg. seat now in common use.

I have shown that it is possible to produce a valve of high lift as regards discharge capacity and low lift as regards the shock at closure. This one

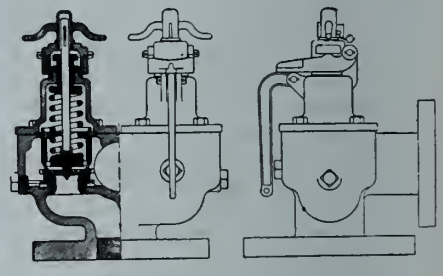

FIG. 21. MARINE VALVE OF APPROVED DESIGN.

feature alone removes the most serious objection to high lift. It is clear that for all of the reasonably high initial lift the valves have a marked faculty to respond to over-pressure. Finally, high-lift valves must come into general use, as the safety requirements in boiler practice must be more economically met than is the case at present. It is distinctly the province of the experienced and unbiased engineer to lay down the rules that will govern future safety-valve installations, but in determining the rules the valves must be considered on a basis of discharge capacity and action rather than lift.

Power Transmission Section

TURBINE GEARING

By D. Street.

IN turbine reduction gears for ship propulsion the width of the gear must of necessity be very great as compared with the pitch and the diameter, and wherever this condition exists the difficulty of maintaining an even working pressure over the whole width of tooth surface is enormously increased. The unavoidable minute irregularities in the cutting of the gear may easily cause the burden of the load to be taken by only a small part of the total width of face at a time; the incidence of the load swaying from side to side of the gear at each rotation; while the torque in the pinion itself, which can never be entirely eliminated, may cause that part of the tooth-face nearest the turbine to take permanently an undue share of the duty. From these circumstances spring the liability of the turbine reduction gears to vibration, noise and unexpected breakage, and the necessity for employing gears of a larger pitch, strength, and weight than would otherwise be necessary.

The problem is, however, by no means insoluble. Macalpine was the first to tackle it seriously. His original arrangement was one in which the pinion was carried in a rocking frame which permitted it to give a little under extra pressure at either side, and so maintain an equality of pressure across the tooth-face. Later hydraulic compensating support was substituted for the mechanical support.

Excellent results have been obtained from this method of automatic self-alignment of the pinion to the wheel, but more recently the problem has been attacked from the other side by building a wheel which will adapt itself to the pinion. The gear is built up of a number of plates machined to a form which gives them the desired degree of lateral flexibility. These plates are put together, engaging solidly at the hub, and also engaging on a narrow edge at the periphery. When so built together, they form a solid cylinder, which can be spirally cut in the ordinary manner. After cutting, the edge engagements are relieved with a small dividing tool, so that each disc is operated independently, and is free to deflect laterally under the side pressure which results from its diagonal engagements with the pinion. The parts are so proportioned that this lateral deflection can at no time involve fibre strains which could possibly cause destructive fatigue. A very small amount of this lateral deflection is sufficient to afford the desired distribution of load, and this amount can easily be given without approaching dangerous periodic strains.

The commercial development of this gear is already well advanced. About 72 sets of the gearing have been applied to turbo-generator drives, and some of these have now been in service one and a half years; about seven sets have been fitted to ships which are now in service, some of them having been long voyages. It is stated that in all of this practical experience no case of trouble with gearing has been developed, and no appreciable deterioration of gears has been observed. Contracts are said to have been closed for machinery for the propulsion of 70 ships, aggregating 215,200 horsepower.

Whether self-equalising devices of one kind or another are really essential to efficiency in turbine gearing depends in some measure upon the degree of accuracy which can be reached in the gear cutting process. While the developments with flexible trunnions and wheels have been going forward, important improvements have been made in the method of cutting large gears, whereby the errors in the master wheels are broken up, and so distributed over the surface of the gear as to be practically eliminated.

VARIABLE SPEED TRANSMISSION DEVICES

By C. T.

IT IS curious to note how after a century or more of intense mechanical development, some of our most widely used machines and mechanical devices are of a type that appears to outrage every mechanical principal. The picking motion of the loom is one of such devices, the combination of motor cycle and side car is another, the sliding gear variable speed device for power driving road vehicles and other machines, is a third.

A study of some of these apparently barbaric survivals leads to the conclusion that their practical advantages outweigh fundamentally their technical deficiencies, and suggests that they are not likely to be superseded by more "correct" devices that will better satisfy the mechanical sense. They may be all wrong, but they give more for a dollar than any alternative arrangement. In most cases they appear to owe their continued existence to the fact that being early established as a standard device, a hundred times more effort has been given to their improvements than to the development of any radically different and, perhaps better method, so that the competition continues to be between an actual much improved and bad thing and a prospective ill-developed good thing.

Whether the sliding change speed gear now employed on the overwhelming majority of road motors belongs to the first or second of these arrangement classes it is as yet too early to say, but the arrangement is too crude to go for a long time unchallenged. Mr. R. E. Phillips in his admirable paper on variable speed gears, read last month before the Institute of Mechanical Engineers, admits that although from an engineer's point of view it is theoretically an embodiment of everything that is wrong, it has been developed to the perfection to which its design has been brought, by the high standard of workmanship employed in its manufacture, and by the use of the highest grade of materials. into a completely satisfactory piece of mechanism. In practice it has proved to be "not so bad as it looks," and it has managed to hold its own for nearly 20 years against many other gears which, theoretically, should give better results. This condition of things he attributes, however, partly to the factor above mentioned, that nothing like the same attention has been devoted to other transmission devices as to this, and partly to the fact that the motors now used are of such a high horse power that at least 75 per cent. of the running is now done on the direct drive.

The amount of effort that has been given to the improvement of the side meshing type of change-speed gear is evidenced by the number of varieties that have been involved. These have been catalogued by M. Rutishauser, an eminent French engineer into no fewer than 9 main divisions and 20 sub-divisions. The most frequent aim of the inventor has been to prevent the undue wear and tear on the teeth of the wheels due to the clash engagement, and the problem has been tackled in many ways.

The side mesher action can, of course, be divided altogether at a price. All that is necessary is to keep the several trains of gears constantly in mesh, and bring into action the particular train required by means of some form of clutch. This method, though theoretically attractive has in practice three weighty drawbacks; it increases the

length and weight of the gear box, it adds greatly to the complexity and cost, and it means that all the wheels are running all the time. A happy compromise is that in which the sliding wheels are mounted loosely on their shafts, and are brought into mesh with the respective corresponding wheels of their trains before they become coupled to the shaft on which they are mounted.

FABRIC BRAKE AND CLUTCH LININGS

By L. E.

THE extent to which fabric has replaced all other substances as a friction material for brake and clutch linings is hardly realized even by engineers. Practically every automobile, for example, now has fabric lining on its clutches and brakes, whilst all the underground railways in London and Paris, as also in the Glasgow subway, now use fabric brake-linings in place of metal blocks. Mr. J. Oswald, of Glasgow, stated that cotton brake-blocks were first tried on horse-cars and were found to have points of very great superiority over wood, especially as regards their efficiency when heated by friction.

Since that time great improvements have been made in the manufacture of friction fabrics. The bonding cement has been rendered more heat proof, and a process has been developed whereby the burning point of the fabric itself is raised 75 per cent.

Fabric lining is of two main kinds—that made of cotton, and that made of asbestos. According to Mr. Oswald, the cotton fabric has the highest co-efficient of friction, i.e., 0.5 to 0.7, and is capable of absorbing much greater work in foot-pounds per sq. in at a given pressure than asbestos material. The co-efficient of friction rises with increased temperature, and is practically unaffected by oil or water. In actual test results obtained by the National Physical Loboratory on cotton material, the work absorbed in foot-pounds per sq. in. per minute was 72,000 dry and 70,000 when lubricated, the pressure being 39 lbs. dry and 160 lbs. lubricated.

The choice between cotton and asbestos is determined in part by the amount of heat that is likely to be generated. The heat limit with cotton is 400 deg. F., and in all cases where this heat limit is likely to be exceeded it is advisable to adopt asbestos material. The co-efficient of friction of this material is 0.3, and it is remarkable that it practically remains constant under varying conditions. Its value lies in its great heat resisting qualities, which recommend its use on exceptionally heavy and prolonged braking or similar duties. Owing to its nature, asbestos material is usually reinforced with brass wire, which makes it more expensive than cotton. Failures with fabric linings are not unknown, but the majority of them Mr. Oswald ascribes to preventable causes: (a) The use of wrong material; (b) to failing to keep the fabric face clear of the opposing face when the brakes are out of action; (c) failing to ensure that the fabric is kept well home when applied, or, in other words, "followed up"; (d) incorrect fixing of linings to the engaging media; also (e) through expecting too much from brakes which have been under-dimensioned by the makers for the duties they have to perform.

Collieries, it appears, are now taking up fabric linings extensively for brakes on main winding engines and haulage gears. Their use saves the rope considerably on account of the smoother action, the upkeep cost is even less than with wood, and there are further advantages in the shape of improved control and speedier working.

The immediate reason for introducing fabric linings for the brakes of the underground railways is interesting. Iron brake blocks give off an amount of iron dust which totals to surprising figures. Three-quarters of a ton of brake-dust per mile has been proved to be produced every month in the New York subway. This dust not only short-circuits the electrical signalling apparatus, and causes stoppage of trains daily, but as it settles on the track the oil from the motors becomes mixed with it and forms a highly inflammable mixture. It was the accumulation of this and the red-hot sparks from the metal blocks which caused the Paris fire a few years ago, in which 480 people lost their lives.

It was partly to prevent these troubles that the cast-iron blocks were abandoned in favor of cotton linings. Since their introduction not a single fire has been reported on any of these railways. Continued use led to the discovery that there was no appreciable wear on the tyres and rails, these being highly burnished. A further very important result is that since fabric linings have been used, rail corrugation and flats on wheels, which commonly existed with the use of metal brake blocks, have disappeared.

BALL BEARINGS

UNDER the auspices of the Society of Engineers (Incorp.) a paper on Ball Bearings was read on April 2 by A. Marshall Arter, F. S. E. A brief resume was given of Prof. Stribeck's investigations.

Before these investigations were made little was known beyond Henry Hertz's theoretical deductions on the contact of elastic bodies. Prof. Stribeck measured the approach of hardened steel balls under compression and found that the admissible static loads varied as the square of the diameter; he also found that ball bearings in which the load is carried at right angles to the axis of rotation of the balls were alone suitable for heavy loads. It was pointed out that the balls in modern ball bearings did not burst, but that the surface flaked out when overloaded, the load-carrying capacity depending upon the elastic limit of the surface of the steel.

The author further pointed out that the ball bearing of to-day could never have been made a commercial success but for the very high degree of accuracy in its manufacture. If a load of 130 lbs. is put upon a ball half an inch in diameter, it is compressed one-thousandth of an inch, and hence if one of the balls in a thrust bearing is one thousandth of an inch larger than the rest, or there is a high place in the race of this amount failure is certain if the normal load of the ball is at all approaching the safe working limit.

The relation of load to speed was dealt with, and it was shown that the safe working load of a ball was reduced on increasing its speed of rotation, in thrust bearings the amount being greater than in radial ones. Prof. Goodman's method of examining balls under a microscope for detecting overloading was explained.

The gyroscopic effects, at high speeds, in thrust bearings was next dealt with. It was shown that there is a certain minimum load necessary to prevent the balls skidding, due to gyroscopic torque, and that there is an absolute limit of speed at which a thrust bearing can be run, namely, when the maximum and minimum loads coincide.

POWDERED COAL AS FUEL

THE condition in which powdered coal must be furnished to produce satisfactory results has been developed to a point where it can be considered as definitely standardized. Not only for the sake of combustion efficiency, but for the sake of more perfect pulverization, the coal should be practically dry, 1 per cent. of moisture being the maximum amount at which pulverizing can properly be effected. One-half of 1 per cent. moisture is the figure which is ordinarily required. Under these conditions the coal when pulverized remains quite fluid, and will break down under the influence of the crushing rolls with much less expenditure of power than when damp.

In order that the fuel may remain suspended in the carrying air and in the furnace chamber during combustion, it is necessary to reduce it to a certain degree of fineness. After a great deal of experimenting this standard has been established as follows: 85 per cent. must pass through a 200-mesh screen and 95 per cent. must pass through a 100-mesh screen.

Much has been printed regarding the quality of coal most suitable for pulverization, but no arbitrary limits can be established as to the proximate analysis most suitable. Broadly speaking, the greater the volatile combustible content the more readily will the coal ignite and burn, and the less dependent will be this process upon the size and proportions of the combustion chamber. As the volatile content decreases, however, more dependence must be placed upon the proportions and location of the surrounding brickwork, in order to maintain the temperature until ignition is complete. Anthracite coal has been burned in a pulverized form, but it must be very finely ground and must be burned in a rather confined space so that the ignition may be prompt and aid be rendered by nearby brickwork during the early stages of combustion.

Steam and Its Generation

WHERE COMBUSTION TAKES PLACE

COMBUSTION of coal takes place partly in the fuel bed and partly in the space above the fuel bed which is commonly called the combustion space. The process of combustion in the fuel bed consists chiefly of the gasification of the fuel. The products of this gasification are mainly CO_2, CO, CH_4, and H_2. The combustible gases rising from the fuel bed are burned in the combustion space by uniting with the oxygen in th eair admitted through the firing door or other openings specially provided for the purpose, and the combustion is complete if the supply of air and the size of the combustion space are sufficient.

Amount of Air Needed

To burn completely 1 pound of coal in a boiler furnace requires about 3 pounds of oxygen or 15 pounds of air. One pound of coal will make a solid cube with 2¾-inch edges. Fifteen pounds of air at atmospheric pressure and temperature occupies a volume of about 200 cubic feet, which is approximately the volume of a 6-foot cube. The volumes of these two cubes show the relative volumes of coal and air that must be fed into the furnace to obtain complete combustion.

How Air Should Be Supplied

In the combustion of coal both the amount of air and the way in which the air is supplied are important. The air may be introduced to the coal at an average distance of several feet or of a small fraction of an inch, the time required for combustion in either case depending on this average distance through which the oxygen has to pass in order to come in contact with the surfaces of the coal.

Thus, for exampple, if a 2¾-inch cube of coal were placed in the center of a 6-foot cubic container filled with air and kept hot, it would burn completely. However, combustion would be slow and might require several hours, although there would be enough air in the container to burn all the coal. The combustion would be slow because the oxygen is suppplied at an average distance of more than 2 feet from the surfaces of the small cube of coal, so that most of the oxygen would have to pass this average distance of 2 feet by the slow process of diffusion, and the products of combustion, chiefly CO_2, would have to be moved away a like average distance by the same slow process.

If, however, the 200 cubic feet of air required to burn the cube of coal were passed at high velocity in thin streams one-sixteenth inch thick over the surfaces of the cube of burning coal, combustion would be rapid, because the oxygen in these streams of air would have to move an average distance of only one thirty-second of an inch to get in contact with the coal. Furthermore ,the oxygen would be greatly aided in passing through this average distance of one thirty-second inch by the eddy currents formed by the high velocity of the stream of air, and would not depend on the slow process of natural diffusion.

Therefore, for rapid combustion, the air must be supplied in thin streams of high velocity over the surfaces of the coal. In general it may be stated that the rate of burning depends entirely on on the rate at which oxygen is brought into contact with the coal.

Features in Furnace Design

The devising of the best method of bringing the oxygen and the coal together, or, in other words, the feeding of coal and air into the furnace, is the dominant feature in the problem of furnace design. As coal must be heated to its ignition temperature before it can be made to burn, another important feature is the method and the rate of heating the coal. There are other important features in furnace design, but the two mentioned are the most important.

BOILER TROUBLES DUE TO FOAMING OR PRIMING

BOILER troubles due to foaming or priming apparently depend to a large extent upon the concentration of alkali salts in the water within the boiler, although silt, organic matter, loosened scale, lubricating oil, character of load and design of boiler all have an appreciable bearing upon this phenomenon. Surface blowing is of course a remedy where it can be applied, and in the majority of cases the proper use of the main blow-off will remedy the trouble by reducing the concentration of salts in the boiler. Many waters, not naturally foamy as they come from their source, can be made so by concentration—by driving off a portion of the actual water and leaving the foaming constituents in greater strength in the boiler; this is the reason why blowing off relieves the foaming, because it takes out of the boiler a portion of the concentrated foaming constituents, and the resulting pumping in of fresh water, to take the place of that blown off, dilutes what is left in the boiler to a point where it will not foam. There are many natural waters of sufficient alkali content to produce immediate foaming whenever the pressure at the surface of the water in the boiler is relieved by the sudden and large use of steam. As there is no chemical treatment that will precipitate alkalies from solution, such waters are to be rejected for boiler use.

BLOWING OFF BOILERS

THE main factors in ordinary boiler-water purification are heat, soda ash, and blowing off, with possible filtration when this can be arranged, as is sometimes done with the hot-process system. The blowing-off process is important beyond the average regard in which it is held. It should be done under low pressure if it is to be fully effective in carrying out the sludge, and blowing under low pressure will reduce the boiler stresses that unquestionably are coincident with rapid blowing under high pressure. If blowing off must be done under high pressure, the blow-off valve should only be "cracked," as a rapid blowing with full valve opening will carry out only a small part of the sediment, because the water vortex or "whirlpool" formed draws clear water down through the sludge to the blow-off opening, thus leaving the main body of the sludge intact.

Undoubtedly some of the troubles recorded as due to scaleforming water are really attributable to the disregard of proper methods of blowing off, and to the pumping in cold water, thereby overstraining the boiler material. Some time after a certain boiler had been cleaned with the soda-ash treatment, the tubes at the rear end began to leak, and the question was asked whether it was the soda ash that was causing the leaky tubes. At first it appeared possible that the cleaning had been too well done, but it later developed that, during the day, hot water from a heater was fed to the boiler, while at night cold water was pumped into it, the plant being one where the engine was operated during the daytime only, while the boiler was in service during the full twenty-four hours. The recommendation was made that an inspirator be used to feed the boiler at night, instead of the steam pump delivering cold water, and the leaky-tube troubles immediately ceased after that was done.

ADVANTAGES AND DISADVANTAGES OF POWDERED FUEL

AS is the case with all new things, the early history of the use of powdered coal is replete with accounts of failures, and this has left an impression on the minds of the engineering public which it will take years of successful application to eradicate. The early experimenters did not understand the necessity of fine grinding, and it would seem that they did not appreciate the influence of furnace design upon the temperature of the resulting gases. The coal was powdered sufficiently fine, however, to develop intense temperatures, even though part of the coal was lost by falling to the bottom of the furnace and being thus removed with the slag and ash.

Insufficient combustion space and the ease with which this fuel can be mixed with the minimum amount of air, combined to produce abnormal temperatures and a direct contact of flame and brickwork. The blowpipe effect of the high-velocity jet acted to melt out the brickwork upon which it impinged. A layer of melted lava, formed by the fusing of both ash and brickwork, accumulated in the bottom of the combustion chamber, and naturally discouraged those who depended upon this fuel for continuous service.

Later on, difficulty was encountered due to the minute particles of liquid slag being carried in suspension and deposited upon the tube sheet or water tubes of the boiler, thereby closing up the flame space and putting the boiler out of action. These effects are particularly observable with certain grades of coal, but noticeably absent with others; and only until recently has research work been carried to a point where any knowledge has been obtained of what causes this trouble and what coals are most suitable for firing in powdered form.

Advantages

Having stated the objections, it is interesting to pay equal attention to the advantages of this fuel. From the view point of the theorist, the use of powdered coal forms one of the best methods ever proposed for the promotion of combustion efficiency and commercial economies. In all transformations of energy there is unavoidable loss, and we are not possessed of apparatus which will gasify coal with 100 per cent. efficiency. In the producer there is a succession of losses which reduce the available heat in the gas to a considerable extent, and in the mechanical stoker there are unavoidable losses due to various forms of incomplete combustion. Only in the case of powdered coal is the actual solid fuel both gasified and completely consumed directly within the chamber desired to be heated. With perfect pulverization the entire mass is burned in suspension, and in actual practice but a small fraction of one per cent. is actually lost in the flue dust or slag pan.

On account of the fuel being conveyed into the furnace by the very air which is afterwards to be used in its combustion, and on account of the diffusing of the coal throughout the air in a cloudlike formation, there is a possibility of a mixture which can be secured by no other means. Each particle of coal is surrounded by a particle of air, and on account of the extreme fineness of the particles practically instantaneous oxidation occurs. The result is efficient combustion, and we have to deal only with the effects of the high temperature thereby obtained. That it is now possible to control this temperature while not sacrificing any material gain due to it, is definitely established. Moreover, the definite control of the amount of air per unit permits of the most perfect variation in the results obtained. It would be impossible herein to enumerate in detail all of the means employed to take advantage of an inherent efficiency of this form of firing.

REDUCING FRICTION BY AUTOMATIC LUBRICATION

By J. W. Peterson

THE only economical method of lubricating bearings consists in supplying as much oil as the bearings will take and of collecting, filtering, and using it over and over again. In passing through the bearings the oil takes up small pieces of metal removed from the bearings by friction, dust, etc., also water from condensed steam, which has leaked past the stuffing boxes. If solid matter and water are properly removed from the oil, it is in a condition to be used over again; therefore the crux of a good automatic system of lubrication is the filter, wherein the oil is restored to its original pure and clean state. An engine or machine equipped with an efficient system of continuous lubrication feeding a stream of oil to all bearing surfaces will run much cooler, wear longer and render the necessity of keying up less frequent than is the case where lubrication is provided by oil cups feeding drop by drop.

In the power plant of a shoe factory the engine-room log shows that before the adoption of continuous stream lubrication it was necessary to key up the pins about once every two weeks, whereas since the oiling system was installed, keying up is only necessary every six to eight weeks. One of the engines in this plant, a 200-h.p. Corliss engine, is equipped with an individual oiling and filtering system, and the make-up oil only amounts to two gallons per month. A further illustration of what can be accomplished with a properly designed automatic system of bearing lubrication is furnished by one of the largest public-service plants in the country, where 30,000,000 kw. are generated each month. The total amount of oil consumed for all the main generating units and their auxiliaries amounts to only 300 gal. per month; and in another plant the actual cost of cylinder and bearing lubrication amounts to only two cents per 1000 kw-hr.

Plant Efficiency

The work done by a steam engine is necessarily divided into three parts; that done against the outside load, which alone is the useful work; that done against the back pressure in the cylinders; and that done against other resistances, the most important of which is friction. Work is also done at the beginning of each stroke in overcoming the inertia of the moving parts, but in a properly designed engine most of this should be restored to the engine before the end of each stroke. In the modern type of engines the mechanical efficiency is very high. In tests of ten new engines of different makes—four simple, four compound, one triple expansion and one quadruple expansion—the mechanical efficiency ran from 93 per cent. to 97 per cent.

In engines not so modern in design and which have been running for some time, the mechanical efficiency may be surprisingly low. In one of fifteen engines tested of this class, which have been operating from ten to twenty years, the mechanical efficiency averaged about 70 per cent. In one case it ran as low as 60 per cent. If the mechanical efficiency is 70 per cent., the recoverable loss would be at least 20 per cent. Take a plant of, say 1000 h.p. The cost of producing a horsepower per year is about $30. A loss of 20 per cent. would be 200 h.p. at $30 per year, or $6,000.

The values for the mechanical efficiencies of steam engines are about as follows: 95 to 98 per cent., rare and unusually high; 90 to 95 per cent., usual good practice; below 80 per cent., decidedly low. Experiments on distribution of friction show that the greatest loss, amounting to one-third or one-half of the total friction, occurs in the main bearings; the next important loss is that of the piston and piston rod, amounting to about 21 per cent. of the total friction. Of this amount 6½ per cent. is chargeable to the friction of the piston and rings against the cylinder walls, and about 14 per cent. to the stuffing box of the piston rod, leaving 1.7 per cent. chargeable to unaccountable losses. The losses due to friction of the working parts of an engine include considerably more than the mere loss of power, namely, the depreciation resulting from wear of bearings, guides, and other rubbing surfaces, and the expense arising from accidents traceable to excessive friction.

Designing Lubrication Systems

There has always been a great deal of guesswork, mystery, and secrecy on the part of manufacturers in regard to the general design and installation of automatic bearing-lubrication systems for power-plant machinery. The lack of general information on this subject has resulted in the installation of many unreliable oiling systems not really suited to conditions existing. The require-

ments of an efficient lubricating system are:

1.—A stream of clean oil supplied continuously at just the points where needed.

2.—A filter which will thoroughly remove all dirt, small particles of metal, and entrained water, and properly cool the oil.

3.—The system should be automatic in its operation and absolutely reliable.

One sometimes hears the statement made that oil becomes worn out through use. This is not the case, as has been amply proved by extensive tests made by several eminent authorities. There may be some slight increase in its specific gravity after it has been used continually, owing to the fact that by increase of temperature some of the more volatile oils are driven off and small amounts of cylinder oil used for lubricating the piston rods, etc., become mixed with the bearing oil; however, the heavier oil is still as good as ever, if properly treated. In some cases the mixture of cylinder oil with the bearing oil, which gets into the system from the piston-rod lubrication, causes serious complications on account of the small percentage of animal fat necessary in the cylinder oil. This in time causes the oil to become emulsified and entirely unsuitable for circulating. To remedy this trouble, there are two alternatives: the first is to dam off the space below the piston-rod stuffing box between the cylinder and the guide barrel so that the cylinder oil dropping from the rod is carried off through the bonnet drips and does not become mixed with the bearing oil; the second is to install a wiping device on the piston rod and lubricate it with bearing oil. I know that a great many engineers believe that only cylinder oil is suitable for lubricating piston-rod stuffing boxes, but we have had very good success in several instances by applying regular bearing oil in this manner.

The lubrication engineer has three alternatives to work upon in the design of a scientific system; he may install a central oiling system in which the main supply of oil is stored at one point and conveyed to the bearings of the various power units and auxiliaries by means of main feed and branch pipes to each machine; or he may make each individual engine, pump, air compressor, etc., a unit by itself, and supply it with its own oiling and filtering system; or he may provide a combination of the two by providing one lubricating system to take care of a group of machines.

In the application of the first system it is necessary to install a large part of the apparatus in duplicate in order absolutely to insure continued operation of the plant. The amount of duplication depends a good deal upon the arrangement of the plant, the susceptibility of the various parts to injury, the value of continued operation and also the ideas of the designing engineer. To insure absolutely reliable lubrication, many plants are now installing individual oiling and filtering systems, so that each unit from the smallest auxiliaries to the largest power unit is equipped entirely independently of all other units in the plant. Practically everything necessary for these individual oiling systems is above the engine-room floor and therefore always in sight and under the care of the engineer or attendant.

Splash System

The so-called splash system used on several makes of high-speed engines has many disadvantages. Usually the engine frame forms an oil reservoir, and the crank dipping into the oil at every revolution throws it out on the rubbing surfaces. It soon becomes saturated with small particles of metal and is entirely unsuited for use over and over again between the rubbing surfaces; furthermore, the oil, being at the high temperature of the engine frame, has practically no ability to carry off heat which may be generated in the bearings, and finally on some engines the steam leaking past the piston-rod packing and condensing in the oil reservoir soon mixes with the oil to such an extent that an emulsion is formed, which has practically no lubricating value. The proper lubrication of engines equipped with the splash system can be easily accomplished by connecting an oil supply line into the reservoir of the splash system and a dirty-oil overflow arranged so that a predetermined level of oil is maintained in the reservoir; thus the dirty oil passes out through the overflow at the same rate at which clean oil is delivered into the reservoir. In this way continuous circulation of oil is maintained and good reliable lubrication is insured. Real bearing-lubrication economy is possible only when:

1.—Every bearing is continually supplied with a stream of clean oil so that the rubbing surfaces float past each other on a film of oil instead of coming into metallic contact, reducing cost of producing power.

2.—When the oil is automatically collected, filtered, purified for use over and over again, reducing cost of attendance and oil.

The foreoing are from papers read before the American Society of Mechanical Engineers.

SAFETY RULES FOR SMALL REFRIGERATING MACHINES

THE city of New York regulations for refrigeration plant installations, whose capacity is under three tons are as undernoted, and in view of the fact that not a few such are to be found throughout the Dominion of Canada, the detail possesses a considerable degree of interest:—

In plants of less than three tons refrigerating capacity using ammonia as a refrigerant, the regulations applying to plants of three tons or greater capacity shall be observed, with the exception that the emergency device discharging to the sewer as shown on the Fire Department drawing (A) is eliminated. Instead of the emergency device, an automatic safety valve set to discharge at not greater than 300 pounds pressure per square inch, shall be located on the high and on the low pressure sides at each point of connection as indicated for the emergency lines. The discharge from such automatic safety valves shall be conducted by continuous piping to the open air, or into a tank of water of capacity to absorb the discharged gas.

Where the discharge is to the open air, the outlet of the pipe shall be turned upwards, and equipped with a suitable diffuser, designed to mix the gas with the air without restricting its flow. The location of the diffuser shall be not less than six feet from any wall in which there is an opening, or at a point ten feet above the roof as remote as practicable from horizontal openings in surrounding buildings, provided more than 30 pounds of ammonia is in the system. If less than 30 pounds of ammonia is in the system the distance of six feet may be reduced proportionately to amount of ammonia in the system.

Where the discharge is into a tank of water, the capacity of such tank shall be based upon the maximum quantity of ammonia in the plant. The capacity of the tank shall be such, that for each 30 pounds of ammonia or fraction thereof there shall be at least 30 gallons of water in the tank at all times. If less than 30 pounds is in the system, then the capacity of the tank may be reduced proportionately to the amount of ammonia in the system. The tank shall be substantially constructed with a hinged cover, or, if it is of an enclosed type, it shall have an inlet and a vent hole at the top. No horizontal dimension of the tank shall be greater than one-half a vertical dimension, and the discharge pipe or pipes from the automatic valves shall be attached so as to discharge at the centre of the bottom and there shall be a valve so situated as to drain the tank of water. The tank shall be as firmly braced, hung, or supported as any other part of system, and be kept filled with fresh water, not used for any other purpose. If there are no valves in the system between the compressor discharge side and the compressor suction side other than the expansion valve, then one automatic safety valve will be sufficient, if located on the high pressure side.

All plants using less than 100 pounds of ammonia in the system will be considered as plants of less than three tons refrigerating capacity. Plants using carbon dioxide as a refrigerant shall be equipped with automatic safety valves as outlined for ammonia plants, but the discharge may be to the outer air or into the room in which the plant is located. Such automatic safety valves shall discharge at not greater than 1,400 pounds per square inch.

Plants using ethyl chloride or sulphur dioxide as a refrigerant, shall be equipped with automatic safety valves as specified for ammonia plants and may discharge into the room in which the plant is located, but ethyl chloride plants using more than eight pounds of ethyl chloride in the system shall discharge to the open air. Such automatic safety valves shall discharge at a pressure not greater than 100 pounds per square inch.

Electricity and Hydraulics

STEEL MILL AND CENTRAL STATION

By K. A. Pauly.

A FACT, not generally appreciated, says K. A. Pauly in the *General Electric Review*, is that the power requirements of the large and even the moderate mills exceed those of any other industrial field of motor application. For example, the main rolls of the rail mill at Gary are driven by six induction motors having a combined rated capacity of 24,000 h.p., with a maximum momentary capacity of approximately 80,000 h.p., and the main rolls of the billet mill at the same works are driven by five motors with a combined capacity of 22,000 h.p. with a corresponding maximum momentary capacity. Then, too, we have the large reversing mills which are driven by motors from 2,000 h.p. to 7,000 h.p. taking peaks from 6,000 to 20,000 h.p. momentarily. In addition to the power taken by the main rolls there are a very large number of smaller motors scattered about the plant for driving all manner of auxiliaries required for unloading the ore and transferring it to the blast furnaces, driving the blast furnace auxiliaries, and for transferring the iron and steel from the time it is drawn from the furnace until it is shipped as finished shapes.

The station load diagram of a steel plant is the result of a combination of load curves of almost every conceivable shape ranging from the extremely intermittent cycles of the large motors driving single stands of rolls and the small motors operating the screw downs, lifting tables, etc., to the more or less constant loads of the larger motors driving multi-stand mills, blast furnace pumps, gas washers, etc. The load factor of a central station supplying a steel mill obviously varies with the magnitude of the plant, although that for small plants is higher than might at first be expected owing to the fact that most small works do most of their rolling in multi-stand mills, roll smaller sections, and take more passes to produce a given reduction. Further, the steel is of such length that it is looped in rolling and passes simultaneously through several stands of rolls, and in many mills several pieces are rolled at the same time, thus producing a much more uniform load than obtains with the large single stand mill.

When power is purchased at a rate which is dependent upon the peak demand as well as the energy consumed or where power is supplied from a comparatively small central station means can frequently be provided for reducing the fluctuations in the load, but as the method of accomplishing this result depends upon a variety of local conditions the various methods will not be discussed here.

Group Relation to Central Station

From the standpoint of the central station, steel mills can conveniently be divided into two groups. In the first are included those companies which operate their own blast furnaces, and in the second group those which purchase their steel in the form of ingots, billets, or slabs, etc., for rolling and fabricating works which purchase the rolled shapes. Although a few of those included in the first group do at present and probably will continue to purchase power to supplement that which is developed locally, the large majority of these companies have made and will continue to make all their own power as a by-product, and many have a surplus to sell. The following figures taken from a paper read before the A.I.E.E. in 1909 will serve to indicate the immense amount of energy available as a by-product incident to the manufacture of steel.

As a result of the reduction of the iron ore in the blast furnace there is produced in the form of so-called waste gases approximately 150,000 cu. ft. of gas having an average thermal value of approximately 90 B.t.u. per cu. ft. Of this approximately 30 per cent. is required for heating the hot blast stoves and approximately 25 per cent. for driving the blast furnace blowing engines, gas washing machinery and auxiliaries used in connection with the blast furnaces and blowing engines, leaving 45 per cent. or approximately 320 kw-hr. per ton of pig iron produced available for general power purposes. Also, many of the large steel plants are manufacturing the coke used in the blast furnaces which reduce the ore at the works and have available as a by-product of the coke ovens approximately 10,000 cu. ft. of gas having approximately 500 B.t.u. per cu. ft., of which approximately 50 per cent. or approximately 130 kw-hr. per ton of coke produced is available for general power purposes elsewhere in the mill. As very nearly a ton of coke is required to produce a ton of pig iron in the blast furnace, the by-product power available for general purposes from the blast furnace and coke oven gases is obviously approximately 450 kw-hr. per ton of pig iron. Also in many steel plants considerable additional power is being obtained from waste heat boilers used in connection with the open-hearth furnaces. While the power from this source is small compared with that from the blast furnace and coke oven gases, it is very considerable when compared with many industrial plants, and has an appreciable effect in lowering the cost of producing power in the large modern steel works.

Type of Equipment Installed

There seems to be a feeling inbred into the minds of steel mill men that 60-cycle equipment is not at all suited to steel mill conditions. The foundation for this is doubtless to be found in the fact that all or practically all of the large steel works throughout the country have adopted 25-cycle as the frequency of their power systems. This prejudice is frequently a serious handicap to the public service power solicitor who is trying to interest the steel company in his goods which he can offer only at 60 cycles. Many of the constant speed auxiliaries about the mill are driven by induction motors and with 60 cycles more speeds are available than with 25 cycles, there being seven speeds from which to choose within the range of 500-r.p.m. and above with the former frequency and only three with the latter. Also most of the equipment, such as motor generators, transformers, etc., are cheaper for 60 cycles and equally efficient and reliable. 25 cycles, however, has considerable advantage over 60 cycles for supplying the slow speed, direct connected, main roll motors, the power factor of such motors usually being higher for the same overload capacities and their costs less.

The difficulty of operating gas engine-driven generators at 60 cycles has also been an important factor in bringing about the adoption of 25 cycles by the large steel plants. There is, however, no fundamental reason why motors cannot be designed for 60 cycles to meet the severe rolling mill requirements, and any one of the large electrical manufacturers will readily guarantee such motors to develop the necessary overloads and to operate within any specified heating limits. The power-factor of the slow speed, 60-cycle machines is as previously stated lower than for 25-cycle units, but this defect can be neutralized by synchronous condensers. It is a fact, however, that most of the mills in the plants which fall in the second group are of the size and type which it is customary to drive either through gearing or rope transmission, thus permitting the use of motors of moderate speeds for which 60 cycles is at

least as satisfactory, if not slightly preferable; so that in general it may be said that 25 cycles possesses little, if any, advantage over 60 cycles as a steel mill frequency for those plants which will consider purchasing their power.

Conclusions Drawn

As in the general treatment of all similar problems no definite recommendations can be made which will conform to all the special conditions which may surround any particular case. However, in summing up, the writer feels safe in drawing the following conclusions from his experience in this field of application of electric power. First, that if for reasons other than the question of frequency, the power for supplying the plant is to be developed locally, 25 cycles should be chosen as the operating frequency, except possibly in the case of some small plants referred to below. Second, that for plants falling in the second group, if reliable power can be purchased at a reasonable rate, which the writer believes is always the case, the mill frequency should be that of the available source of supply whether 25 or 60 cycles and the necessary power purchased, unless for reasons other than those having a direct bearing on the power problem, it is considered expedient to generate rather than purchase power. It is conceivable that it might be to the interest of the steel company to operate its own plant, although from power considerations alone this would seem unwise, and in such cases the adopted frequency should in general be the same as that of the local public service company so that in the event of a breakdown assistance can be obtained from the local company.

DIESEL ENGINES v. STEAM TURBINES

A COMPARISON of the cost of generating power by means of Diesel engines and steam turbines, together with a discussion of the different factors governing the profitable use of either type, is given in a paper read by Herbert Haas at the Arizona meeting of the American Institute of Mining Engineers. The author says that in places where neither cheap coal nor water power is available, and the price of oil fuel is increased by cost of carriage, the Diesel engine will become a prime mover of increasing importance. Where water is scarce the Diesel engine also shows to advantage, because about twelve times as much water will be required for condensing purposes with steam turbines under general conditions as is needed for jacket cooling of the two-stroke engine, while engines of the four-stroke pattern require only one-twentieth of the water. The following table of costs of generating power with four 2,000-kilowatt Sulzer-Diesel engines, direct-connected with alternators and exciters, is based on a fuel cost of $1.25 per barrel of 320 lb., and lubricating oil cost of 35 cents per gallon:—

TABLE I.—COST OF GENERATING POWER WITH FOUR 2,000-KILOWATT SULZER-DIESEL ENGINES DIRECT CONNECTED TO GENERATORS AND EXCITERS.

	Full load 12,000 h.p. 8,000 kw.	¾ load 9,000 h.p. 6,000 kw.	½ load 6,000 h.p. 4,000 kw.	¼ load 3,000 h.p. 2,000 kw.
Kw. hr. per year	70,000,000	52,500,000	35,000,000	17,500,000
Barrels	140,000	105,000	70,000	35,000
	Cost per year	Cost per year	Cost per year	Cost per year
Fuel cost	£35,000	£26,200	£17,500	£ 8,750
Labor	3,780	3,780	3,780	3,780
Lubrication	6,130	4,599	3,066	1,533
Maintenance	1,440	1,440	1,440	1,440
Total direct	£46,350	£36,019	£25,786	£15,503
Interest and amortisation	17,280	17,280	17,280	17,280
Total cost	£63,630	£53,299	£43,066	£33,783
Cost per kw. year	7.9	6.6	5.4	4.2

The kilowatt-year is equivalent to 8,760 kilowatt hours. Three units work continuously, and one acts as a stand-by and the cooling water in circulation for 9,000 horse-power, working continuously, amounts to 8,000 to 11,000 cubic feet per hour with re-cooling arrangements.

In table II. the costs of operation under similar conditions, with power generated by two 6,000-kilowatt turbines, are shown. The turbines work with steam at 180 lb. pressure per square inch, steam temperature 620 deg. Fah., inlet temperature of condensing water 60 deg. discharge temperature 75 deg. Fah., quantity of cooling water per 6,000 kilowatt-unit, 74,000 cubic feet per hour. One generating set works continuously at full load and the other is a stand-by:—

TABLE II.—COST OF GENERATING POWER WITH TWO 6,000-KILOWATT STEAM TURBINES.

	Full load 8,000 kw.	¾ load 6,000 kw.	½ load 4,000 kw.	¼ load 2,000 kw.
Kw. hr. per year	70,000,000	52,500,000	35,000,000	17,500,000
Barrels	300,000	210,000	150,000	83,700
	Cost per year per kw. hr.	Cost per year per kw. hr.	Cost per year per kw. hr.	Cost per year per kw. hr.
Fuel cost	£75,000	£52,400	£37,400	£20,925
Labor, etc.	5,000	5,000	5,000	5,000
Maintenance	1,440	1,440	1,440	1,440
Total direct	£81,440	£58,840	£43,840	£27,365
Interest and amortisation	17,280	17,280	17,280	17,280
Total cost	£98,720	£76,120	£61,120	£44,645
Cost per kw. year	12.2	12.6	15.2	22.3

The selection of two 6,000-kilowatt rather than three 3,000-kilowatt steam turbines is made on account of the greater efficiency of the 6,000-kilowatt sets, while the selection of four 2,000-kilowatt Diesel engine units is justified by the author on the ground that larger engines are not any more efficient in fuel economy, and the relative much higher cost of this prime mover makes it a good policy to reduce reserve capacity to a safe minimum.

Prime Mover Selection Considerations

The author concludes that in general the selection of either type of prime mover will be governed by the following economic considerations:—

1—Fuel is of chief influence on the total power cost, where both the B.t.u. price and load factor are high. These conditions favor the use of the Diesel engine.

2—Interest and redemption (amortisation) are of chief influence on the total power cost with low B.t.u. price and low load factor. This applies particularly to stand-by plants, which are operated only occasionally or have to supply recurring peak loads. The installation cost of such plants must be kept as low as possible so as to avoid heavy capital charges distributable over a relatively small kilowatt-hours output of the station. Such conditions favor the steam turbine.

3—Exceptions to (2) are cases where the constant and instant readiness of the Diesel engine give it preference, and installation cost is of secondary importance. Here it is necessary to balance the cost of keeping boilers under steam continuously against the difference of interest charges of steam turbine and Diesel engine plants.

4—For power plants erected at the source of the fuel, either in the oilfields, or at the coal mine, prime movers will be selected, costing least to instal, i.e., steam turbines, since fuel expenditures will weigh less than interest and redemption charges.

5—In many cases combination plants using Diesel engines for supplying the continuous and nearly constant main load, and steam turbines for furnishing periodically occurring peaks by the use of high-duty boilers with large water and steam spaces, capable of being forced when necessary, will prove most profitable.

6—Steam power will remain the cheapest power wherever waste-heat gases are available, as, for instance, gases from reverberatory smelting furnaces, where nearly one-half of the fuel used in smelting can be utilized for steam generation. Nearly 3,000,000 B.t.u. for every ton of charge smelted are thus available

for steam generation, or about 150 horsepower hour per ton of charge.

7—Up to capacities of 1,000 horsepower steam turbines can compete with Diesel engines only in special cases, such as supplying exhaust steam for heating purposes. For such small units, particularly for greatly varying loads, reciprocating steam engines are preferable. For larger plants, from 1,000 to 10,000-kilowatt capacity, careful analysis must be made of the relative advantages of Diesel engines and turbines, a knowledge of the load factor, fuel prices, and water conditions being necessary. For power plants larger than 10,000 kilowatts, using units from 6,000 kilowatts upward, steam turbines have the preference, unless a combination of high load factor, high fuel cost, and poor water conditions favor a Diesel plant.

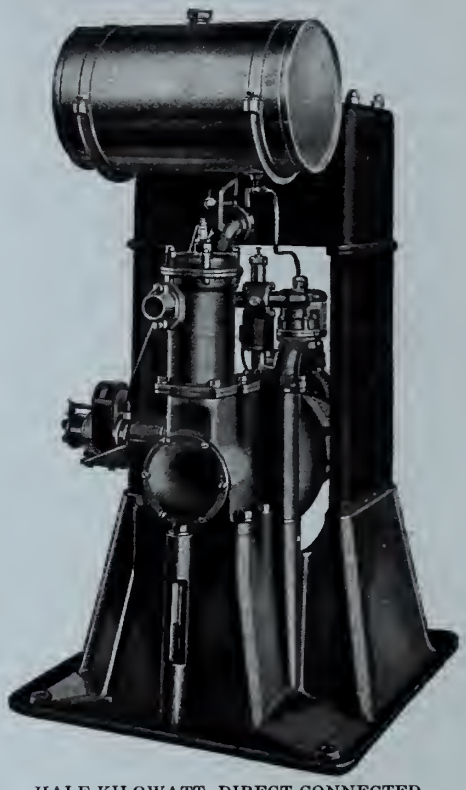
VERTICAL VS. HORIZONTAL DIESEL ENGINES

ONE of the outstanding features of Diesel-engine manufacture in the United States, says S. B. Daugherty in an A. S.M.E. paper, is that, in general, those manufacturers who have done their own designing have brought out horizontal engines, while those who are building vertical engines have purchased the designs abroad. The advantages of the horizontal engine, as enumerated by a concern with an established reputation as builders of vertical engines are: lower price; easy survey and convenient attendance; better distribution of stresses on the crankshaft and main bearings; better lubrication of bearings; better lubrication of piston; easier cleaning and repair work, especially to pistons, which can be taken out without removing the cylinder head and the valve gear; reduced height of engine room, as all pipes are laid in trenches under the floor and do not obstruct the room.

The Piston Detail

In a comparison of vertical and horizontal Diesel engines the detail most discussed is the piston. Vertical builders call attention to the weight of the piston, and the side pressure thereby produced on the cylinder bore, in the case of the horizontal engine. The fact that the first Diesel engines were built vertical, and that excessive height was undesirable, probably led to the use of trunk pistons. For the same reason a connecting rod of a length but slightly more than five cranks has been used in vertical engines. An analysis of the forces prevailing throughout the cycle of operations shows that the side pressure on the cylinder walls, due to the angularity of the connecting rod, is far greater than the pressure due to the weight of a piston, even though the piston lies horizontally. Any increase in connecting-rod length means a proportional decrease in the side thrust. Ordinarily an increase in the length of the connecting rod of one crank length decreases the side thrust an amount equal to the weight of a piston and wrist pin, or, in other words, a vertical trunk-piston engine with a connecting rod five cranks long is subjected to about the same side pressure on the cylinder wall as a horizontal trunk-piston engine with a connecting rod six cranks long.

It makes but little difference whether an engine is built vertical or horizontal so far as side pressures are concerned. The advantage of the horizontal engine in general, and the crosshead type in particular, is in its superior accessibility. In the case of a vertical trunk-piston engine it is necessary to practically dismantle the engine in order to get at the piston, piston rings, or wrist-pin bearings. In most cases the valve gear



HALF-KILOWATT DIRECT-CONNECTED GASOLINE-DRIVEN LIGHTING AND POWER SET.

and the cylinder heads must be removed, the connecting rod must be disconnected at the crank pin, and the piston and piston rod then lifted out through the cylinder.

Compare this procedure with that necessary in the horizontal engine: The sheet-steel crank splasher is removed; then the connecting rod is disconnected at the crank pin in the case of a trunk-piston type, or more simply at the wrist pin if the engine has a crosshead, and the piston is then removed from the open end of the cylinder. The actual time required to remove a piston and cross head of a 19-in. by 33-in. engine was twenty minutes. The piston was wiped clean and replaced in thirty minutes, making the total shut-down fifty minutes, as compared with about one day of ten hours to accomplish the same thing in the case of a vertical engine.

½ K.W. DOMESTIC LIGHTING AND POWER PLANT

THE problem of designing a home-size lighting plant is one which has engaged the attention of electrical engineers for some time, with varying degress of success. Belt-driven and direct-connected sets with self-starting arrangements, etc., have been available to small power users such as farms, country churches, camps, railroad stations, and isolated inns and boarding houses, but the designs of the set illustrated herewith have made departure from the present tendency by discarding belts, storage batteries and starting devices, and have developed a unit which is claimed to be capable of running continuously night and day if required, the cost of the comparatively idle extra running being less than that of storage battery depreciation.

The engine end of the Uni-Lectric lighting and power plant is shown in the engraving, the rated capacity of the set being 500 watts (½ k.w.) at 110 volts, direct current. A generous overload capacity renders it capable of running fifty 15-watt lamps, or any combined light and power load up to 750 watts, so that two motors of ½ horse-power each may be run from it.

The well-known efficiency of the sleeve-valve type of engine over long periods of continuous operation induced the designers to adopt this principle. The 4 stroke-cycle is employed with a single cylinder of 2¼ in. bore and 3 in. stroke. The sleeve, however, is of the revolving type which thus leaves the piston and piston rod as the only reciprocating parts in the entire construction. The cylinder casting is provided with exhaust and intake ports, and the sleeve which is carefully ground to a proper fit is arranged with two diametrically opposite ports for registration with the cylinder ports. The piston is located inside the sleeve and reciprocates in it as though it were the true cylinder. The sleeve is driven at only one revolution to four revolutions of the crankshaft, its two ports acting alternately as exhaust and intake.

The cylinder, as can be seen, is bolted to the crank case, which carries a single long crank shaft bearing; the armature shaft is tapered and fits into the end of the crank shaft so that it becomes integral therewith, the free or commutator end of the armature shaft being carried in a ball bearing. Forced automatic lubrication by pump is provided to all moving parts except this ball bearing, which only requires attention every month or so.

The entire generator is housed in a casing bolted to the end of crank case, and cooling water hopper and fuel tank are conveniently mounted overhead. Magneto ignition and automatic carburetor and governor are provided, the net weight of the apparatus being 375 lbs., and floor space occupied 24 x 25 in., with a height of 45 in. The Waterman Motor Co., Detroit, Mich., are the builders of this outfit.

REFRIGERATION DEPARTMENT

REFRIGERATION AND REFRIGERATOR INSULATION*

THE idea seems to prevail that a refrigerator door should have bevelled edges, and that these bevelled edges make a very tight door. How this idea originated it is beyond the writer's power to divine. As a matter of fact, such a door can be tight only if it happens to be very carefully fitted. As soon, however, as the moisture begins to have its inevitable effect, the door cannot by any chance be tight. Furthermore, if the hinges yield at all, as they are certain to do with a heavy refrigerator door, it will never be tight, even though it does not warp at all.

In the writer's opinion there is only one practical way to make a tight refrigerator door, that is, to have a plane surface come up against a plane surface with a flexible gasket between these two surfaces. It may also be possible to have a pair of such surfaces, or, rather, two pairs of such surfaces with gaskets between them, making an air pocket between the two seals. If this arrangement is used the door can sag considerably without causing any serious binding or failure in tightness. This matter of a satisfactory refrigerator door cannot be emphasized too much.

Refrigerating Capacity

In estimating the capacity of a refrigerating machine required to take care of a given refrigerator, it is not sufficient to calculate the heat loss through the insulation of the refrigerator. In fact, this loss in many cases is very much smaller in proportion to the total loss than the average engineer realizes. It is proportionately so small, in fact, in the case of ordinary household refrigerators, after comparing the ice consumption in well and in poorly insulated boxes, use very low grade insulation in their stock boxes. Their custom, in general, is to reduce the size of the air passages leading to and from the ice compartment to a very small area and thus, by restricting the flow of air over the ice, they reduce the meltage to a minimum. The average purchaser of one of these refrigerators is more interested in economy of ice than he is in the temperature to be secured in the box. He assumes that the temperatures are all right, but he knows each month whether or not the economy is right, when the iceman's bill comes in.

*Part II. of a paper read at the 24th general meeting of the Society of Naval Architects and Marine Engineers, New York City.

Heat enters a refrigerated compartment through five avenues: — First, through the walls, i.e., through the insulation; second, in warm goods; third, by the interchange of air through the opening of doors and by air leaks through defective insulation or through defective doors, cold air being heavier and immediately flowing out when doors are opened; fourth, from lights or from the heat of the bodies of workers; and fifth, from any change of state occurring in the goods, such as freezing, fermenting, etc. In large rooms these various losses of heat should be analyzed separately. In small refrigerators, such as those for hotels, kitchens, private homes, the average galley refrigerator and so on, a rough rule that gives quite as accurate result as a more elaborate analysis allows for a certain number of British thermal units per cubic foot of refrigerator per 24 hours, for instance, 1300 British thermal units per cubic foot for an average pantry refrigerator. If the box is located in a kitchen, as in a hotel or restaurant, it is safer to allow about 600 British thermal units; and if the kitchen is especially warm, as many galley kitchens are, 900 British thermal units are safer, especially if the boxes are small.

For butchers' coolers or large boxes in hotels, i.e., large storage boxes from 6 feet by 8 feet to, say 10 feet by 15 feet, a safe allowance is, approximately, 200 to 250 British thermal units per cubic foot for 24 hours. In climates varying appreciably from the temperate zone, corresponding allowances must, of course, be made.

Suggested Scheme of Analysis

In general, the size of machine for a given refrigerator has to be decided upon before the refrigerator is put into service. On the other hand, where an existing ice-cooled refrigerator is to be cooled mechanically, one check on the size of the machine required is given by the amount of ice which has been used. This check is, however, more likely than any other to lead to wrong conclusions unless the figures are properly analyzed. The following is a suggested scheme of analysis:—

First, determine the average daily ice consumption for the summer months—say July or August—from the actual weighing of the ice, or from the ice bill.

Second, determine as accurately as possible the average temperature that was secured by ice in the refrigerator. This will usually be from 55 to 60 degs. and, although it is commonly stated as anywhere from 40 to 45 degs., these lower figures are so seldom obtained day in and day out as to practically warrant the statement that they are never reached. It is only with a full ice chamber and with the box closed for long periods that such low temperatures can be secured, and even under these conditions the average temperature will still run well above these figures.

Third, calculate the heat inflow through the insulation with the temperature in the box as actually observed or as assumed, and with the average summer temperature prevailing outside. The difference between the heat inflow through the insulation and the total heat actually absorbed by the melting of the ice is the amount of heat entering the box fro mother sources than through the insulation. This excess of heat ordinarily occurs during the day time only, i.e., when the box is being opened, since at night the box remains closed. A machine, to be of sufficient capacity to produce the temperature actually obtained with ice, therefore, must be large enough to absorb the heat inflow through the insulation and also the additional heat entering during the daytime from other sources, i.e., to take care of this entire load during the day. Stated in another way, the machine must be large enough to absorb, during the daytime part of its run, half of the total insulation loss plus all of the balance of the loss.

Fourth, a further fact to be taken into account in determining the proper size of machine is that the temperatures which are obtained with ice are not satisfactory. If they were satisfactory, one of the greatest reasons for putting in cooling machinery would be void. Where a temperature of 55 degs. can be obtained with ice, 35 to 45 degs. will be demanded of mechanical cooling. Therefore, the machine size must be further increased in proportion to the number of degrees difference of temperature required. For instance, if the outside temperature is 71 degs. and the temperature desired is 35 degs., where the ice temperature has been 55 degs. the machine size must be increased in the proportion of 71 minus 35, divided by 71 minus 55, or 2¼ times.

Fifth, furthermore, if the cooling machine were installed in accordance with these figures it would handle average summer weather conditions, but would be insufficient for extreme hot weather, the most important condition to be met by refrigeration. It is necessary, there-

fore, to further increase the size of the machine in the ratio of the difference between the maximum summer temperature and 35 degs. and the average summer temperature and 35 degs:

Sixth, one further allowance should be considered, namely, the fact that in many cases, for one reason or another, it is either impossible or undesirable to operate the machine except during certain parts of the day. The machine size must, therefore, be increased by as much as may be required to produce the desired amount of refrigeration in the short time available.

Seventh, and finally, if the machine is not placed directly beside the box to be cooled, allowance must be made for the heat inflow into the insulated cold main. The amount of heat entering from this source is often of considerable importance, particularly with small machines.

Individual Case Application

When one comes to apply these figures to an individual case the size of machine is apt to work out so large as to be rather startling. There are so many elements that are entirely uncertain, such as the kind of workmanship in the insulation, the amount of leakage through doors, the kind of care the refrigerator will be given, the probability of the doors being left more or less ajar; there are, in fact, such a multitude of very uncertain elements that considerable leeway ought to be allowed in the size of machine.

Where the amount of refrigeration is large, as in a good-sized storage warehouse, one can always throw a large part of the machine capacity to any given box where special need exists. To do this with a small machine would almost certainly rob some other box, if indeed there happened to be another box to rob. One cannot emphasize too strongly, therefore, the importance of having ample capacity in small refrigerating machines. In installing cooling surface in refrigerators it is often necessary to arrange the layout as one can, rather than as one would like to do it. If efficiency in the use of the cooling surface is the only consideration, a lower temperature can be secured in the refrigerator by placing the coils directly on the ceiling than in any other way. An arrangement of this kinds, of course, is sure to keep the box rather moist and, except in rare instances, is not permissible.

In a great many cases the only thing that can be done is to place the cooling surface directly on the walls of the box. There are, with this arrangement, several disadvantages. In the first place, goods that are stored on shelves close to the coils are apt to be pushed against them, and constant care is essential, and unfortunately rarely given, to keep the coils clean. Goods placed near the coils are also colder by far than goods toward the middle of the refrigerator. There is no direction given to the circulation of the air—that is to say, there is apt to be considerable eddying between the rising and the falling currents of air so that the circulation is often rather sluggish.

Deposit of Moisture

There is often considerable trouble from deposit of moisture on the walls of the box in this arrangement. When the box stands closed for a considerable period, the walls and ceiling become quite cold by direct radiation to the coils. When the door of the refrigerator is open, the cold air in the box rushes out, and warm air, often heavily laden with moisture, comes in. This warm air strikes the surfaces and immediately deposits moisture, often to so great an extent as to cause serious dripping from the ceiling on to the stored goods. Frosting on the walls is of course caused in the same way, but is not so serious on account of the element of dripping on to goods being absent.

This deposit of moisture on the ceiling of the refrigerator is especially apt to occur at a point farthest from the cooling surface on the walls. This is due, undoubtedly, to the sluggish motion of the air in this part of the refrigerator, the circulation being considerably better nearer the coils. The air, which has been more or less dried by the deposit on the cooling surface, gradually dries the surface with which it comes in contact as it circulates.

The best arrangement of cooling surface in the refrigerator is either to place it in a loft above the box, i.e., above the storage compartment, or in a space alongside of this compartment, with ample air passages to permit the circulation of the air between the two compartments. This arrangement is, of course, inefficient as regards the use of the cooling surface, but gives a very much more satisfactory refrigerator. Moisture is deposited on the coils, the air passes back to the refrigerator partially dried, and, if the box is properly proportioned, the air in passing over surfaces of the refrigerator, as well as over the goods, dries them and keeps them in good shape.

Large Air Passages

Comparatively few refrigerator builders have any realization of the vital importance of having large air passages, or, if the builders of ordinary household refrigerators have this appreciation, they use it to the disadvantage rather than the advantage of their design so far as its use to the purchaser is concerned. As already pointed out, if the air passages in a refrigerator are choked down, there will be little circulation of the air, and the refrigerator will therefore be economical of ice. It will be a refrigerator, however, in name only. The force that causes the circulation of air in a refrigerator is extremely minute, being only the difference of weight between the air in the coil compartment and that in the same height of the food storage compartment. If there is a difference of even, say 15 degs. in the temperature between the two compartments the excess weight in the one over the other is obviously extremely slight.

The writer had an opportunity several years ago to make an experiment on refrigerator temperatures that brings out this point very clearly. The cooling surface of a section through the refrigerator, which was about 8 feet wide and 6 feet high, was located in the middle of the apparatus with a baffle plate on each side of it, and the passages for the air were identically the same on both sides, except that the space leading from the storage compartment to the coil surface at the left was 3 inches and that at the right was 4 inches. The difference of 1 inch in this one dimension made a difference in the temperatures observed at the points marked A and B of one degree, throughout a week test.

When one considers that the average household refrigerator has air passages from 1 to 2 inches (rarely more than this) in depth, and when the average large refrigerator has only 3 or 4-inch passages, in a very great many cases, the desirability of further attention to this element in the design of refrigerators is apparent.

Refrigerating Machines

The writer will not attempt any elaborate description of the various types of refrigerating machines that are used in marine work. As a matter of fact, practically every type of machine that is built has been given more or less trial in this service. He will only attempt to call attention to a few of the considerations that seem important in determining the type of machine suitable for any given installation.

Air Type

For a number of years the only refrigerating machine that seemed entirely safe for use on board ship was the air machine, especially as embodied in the Allen dense air machine. The skill required in the operation of these machines and their enormously high cost of operation was more than counterbalanced by the freedom from danger from escaping gases that they gave. There was no need to carry a supply of flasks containing gases at high pressure; there was, therefore, freedom from any danger to the ship from the presence of these gases, and there was no danger that the machine would be shut down from lack of chemicals. There was, of course, considerable danger of derangement of the machine in case it was not skillfully handled, and, as already suggested, the cost of operation was so high that, except for relatively small sizes of machines, the use of this design of machine was prohibitively expensive.

Ammonia and Carbonic Acid Types

In cases where the escape of gases would not be serious and where, on the other hand, cost of operation would be an important item, and where large quantities of refrigeration were required —especially in cases where a separate engine-room could be provided for the machine—the ammonia and carbonic acid type of machine has been the ruling type. In the merchant service there are a number of these machines placed directly in the main engine-room. It is unnecessary to dwell upon the matter of locating the machine in this way to the engineer who has been through the experience of an accident or the unexpected escape of gases. For the engineer who

has not been through an experience of this kind, discussing the subject will not carry great weight. Human nature nature seems very much to prefer the process of locking the stable after the horse has been stolen.

As has already been indicated, the ammonia or the carbonic-acid type of machine is undoubtedly the best type of machine for cases where the capacity required is considerable, and where a separate engine-room can be provided. In the choice of machines for this service there is a selection to be made between the open type of machine in which the stuffing box is arranged on the piston rod, and the enclosed crank case type. In larger units the open type of machine is, of course, almost invariably used. In the writer's judgment this type of machine is distinctly better for the small as well as for the larger work. The open-type machine has the advantage in the matter of taking up wear and constantly and readily keeping the machine in its best state of efficiency. It has the further advantage of not wearing nearly as rapidly as does the enclosed crank-case design.

Detail Features

Consider, first, the matter of the stuffing box. Where this is on the piston rod, and especially where the stuffing box is fitted with springs and with an oil lantern connecting to the low-pressure side of the machine, it is possible to run with a stuffing box so loose that the outer gland moves back and forth against the springs with each stroke of the piston and yet with no odor of ammonia discernible. The wear on the piston rod in this case is relatively small. Compare with this the wear on the stuffing box on the shaft of an enclosed crank-case machine. The wear on this shaft is concentrated at one particular point. The stuffing box is ordinarily not difficult to keep tight or approximately tight, but when it comes to replacement the piston rod of the open-type machine is a very much less expensive part to replace, and one very much more easily replaced than is the crank-shaft of the enclosed-type machine.

The capacity of a refrigerating machine, of course, falls off with increase in the clearance in the cylinder. A moment's consideration will show very clearly the simplicity of adjusting clearance in the open type of compressor and the very serious difficulty in making the corresponding adjustment in the enclosed-type machine.

Audiffren-Singrun Machine

Turning now to the Audiffren-Singrun refrigerating machine, in this type of machine the problem of a stuffing box is met by closing all the working parts of the machine within a hermetically sealed drum. The machine consists of a shaft with a pulley at one end, a drum at the other end, and a second drum at the middle of the shaft. The machine is carried in two bearings, one on either side of the central drum, and revolves with the central drum in contact with flowing water. The compressor, which is reduced to its simplest element because of its peculiar situation, hangs loose on the shaft inside the condensor drum and is held in position by means of a counterweight. The dumbell is sent out from the factory completely charged and ready to operate. The air is entirely exhausted and a charge of sulphur dioxide and a pure neutral oil is admitted, after which the machine is hermetically sealed. The working parts are thus constantly lubricated, and the pressure in the condenser is constantly forcing oil between the working surfaces of the compressors. Oxidation of the lubricating oil cannot occur as there is no oxygen present. It is impossible to draw air into the machine because the dumbbell is hermetically sealed. No dust can get access to the working parts, and, as a consequence, the wear on these machines is reduced to a minimum.

Operation Features

In a machine of this type the gas enters the compressors in practically a saturated condition. In consequence of this the compressors always operate automatically at maximum capacity, and there is no superheating of the gas with consequent loss in capacity. The brine returning to the machine from the cooling surfaces in the refrigerator overflows from the inner tank to the outer or surge space, whence it is drawn by the pump and again circulated through the cooling surfaces. The arrangement of inner and outer tank avoids the possibility of spilling of brine with the motion of the ship. A similar arrangement is provided for avoiding any spilling of condensing water in the condenser tank.

Where ice is required in addition to cooling refrigerators, either one of two arrangements has been used. One arrangement consists of closed coils through which the brine circulates with an auxiliary bath of brine in which the ice moulds are placed. This latter arrangement of ice making tanks cannot be placed high enough to insure flow of the brine back to the evaporator or brine-cooling tank. It has the disadvantage, of course, that the brine has to be circulated at a lower temperature than in the case of the open system.

With this refrigerating machine it is possible to place the machine close to the refrigerator on account of the simplicity of its operation and the very small amount of care that is necessary, since there is no necessity for watching expansion valves or stuffing boxes, or anything of that kind. This, of course, means a considerable saving in heat losses through the piping, which losses are in the case of small work, such as refrigerating work on board ship ordinarily is, quite important. The condenser tank in this installation is practically identical with the usual tank for standard marine work. The brine tank, however, is provided with a labyrinth where the shaft of the machine enters the tank to prevent spilling of brine.

The circulation of the brine through the coils in the refrigerator is secured by the action of the machine itself, which throws the brine into the hood or scoop whence the brine flows by gravity. The design of the refrigerator has also been carefully worked out, so that in storing goods in the box it is very difficult, if not impossible, to entirely block the air passages. Space is also provided so that cooling coils for drinking water may be placed directly below the brine coils, and in a number of instances this space has been so utilized.

INCREASED TAX ON WAR PROFITS

THE resolution brought down by the Minister of Finance, in the House at Ottawa, to give effect to the proposals contained in his budget speech provides:

1—That in any business taxable under the Act where the annual profits exceed 15 per cent. per annum, the tax shall be increased to 50 per cent. with respect to all profits in excess of the said 15 per cent., but not exceeding 20 per cent. per annum, and where the profits exceed 20 per cent. per annum the tax shall be increased to 75 per cent., with respect to all profits in excess of the said 20 per cent., and such increases as the tax shall be levied against and paid by the person owning such business for each and every accounting period ending after the 31st day of December, 1916.

2—That for the purposes of the said Act, the actual unimpaired reserve, rest or accumulated profits shall, at the commencement of an accounting period by an incorporated company, be included as part of its capital as long as it is held and used by the company as capital.

That any enactment founded on this resolution shall be deemed to have come into force on and from the 18th day of May, 1916.

3—That the tax shall be paid each year within one month from the date of the mailing of the notice of assessment.

4—That with respect to every business liable to taxation hereunder the period for which the returns shall be made and during which it shall be liable for assessment shall be at least thirty-six months, commencing with the beginning of the first accounting period ending after the 31st day of December, 1914, or for such less period as the business may have been carried on from the beginning of the said accounting period to the end of the period for which the said tax may be levied under the said Act.

The following table illustrates the division under the new Profits Taxation Act of a company's profits between the company and the Government:

Profit	Company	Government
10 p.c.	9¼ p.c.	¾ p.c.
15 p.c.	13 p.c.	2 p.c.
20 p.c.	15½ p.c.	4½ p.c.
25 p.c.	16¾ p.c.	8¼ p.c.
30 p.c.	18 p.c.	12 p.c.
50 p.c.	23 p.c.	27 p.c.
100 p.c.	35½ p.c.	64¼ p.c.
200 p.c.	60½ p.c.	139½ p.c.

Trouble Either Way.—"I understand your automobile has gotten you into trouble."

"It's always getting me into trouble, one way or another," replied Mr. Chuggins. "When it runs, I get arrested for speeding. When it refuses to run, I get arrested for profanity."

CERTIFICATES AS GUARANTEES OF ABILITY

THE demand for efficiency, now more urgent than ever before, might well be advanced as an argument for indicating, in a suitable manner, the degree of qualifications possessed by individuals where their possession of ability in certain lines is the prime reason for their employment. Power house operatives, from chief engineers down to coal trimmer, can perform team work of a most valuable nature, or on the other hand, by working at cross purposes or by studied indifference increase operating costs tremendously.

The possession of a certificate issued by a Government department may testify that the holder possesses certain experience and knowledge which qualifies him to hold a certain position, but another with a similar certificate may be capable of holding a much more responsible position and yet be unable to obtain official evidence of his superiority.

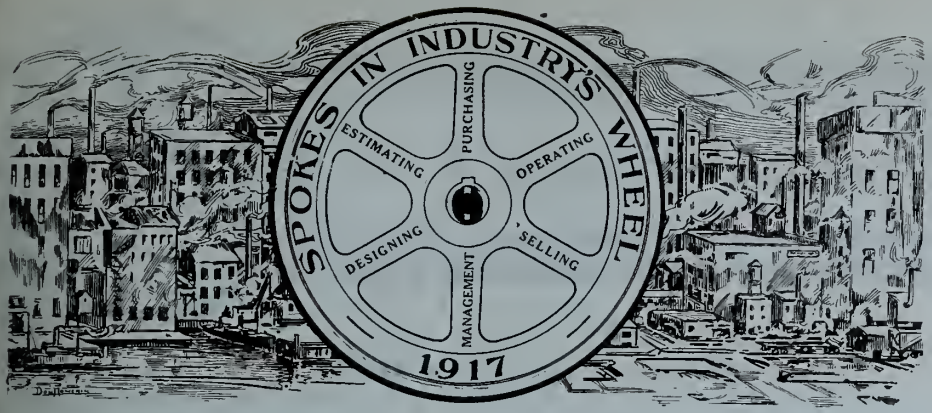
Power house engineers are just as human as other people, and take as high a pride in their work individually, but ability is no more uniform with them than with other crafts, and the employer who wants the best has no means of judging except by "trying out," a process which must be repeated each time a vacancy occurs unless suitable candidates for promotion are available.

Requirements of present-day power plants are often such that personal ability is required much in excess of that indicated by a "flat grading," so to speak, which must of necessity be moderate enough to cover the most insignificant of operating requirements. The ambitious and experienced operator can be justly excused if he feels that fuller recognition of his greater fitness should be given. Such action in the form of graded certificates would be to the benefit of the employer no less than to the engineer as an individual or to his profession as a whole.

CANADA'S 1917 BUDGET

IT may be said of our Finance Minister's Budget, brought before the House of Commons, Ottawa, during the present month, that its substance is nothing more or less than an expansion of the scheme of taxation of war profits, now operative. In another section of this issue a condensed detail is given of its leading provisions. Considered either apart from or in conjunction with the present war taxes, or an income assessment, there are other taxes which, if made immediately effective, would help to pay our war debts as we go with no other effect than checking public extravagance of which there is so much evidence.

If the tax on automobiles were increased by $10 there would be no burden on anyone who could not well bear it. The amount would be large and could be readily collected. In fact it is a tax which might well be continued after the war and the fund used to the betterment of the national highways. The tax on theatre tickets could well be doubled, its proportions being such that its imposition would be least felt by those concerned. It is a tax which would be no great burden to judge by the crowds attending houses of expensive entertainment particularly. Even if the crowds were decreased there would be no great harm done, besides the public spirit would be directed to things more appropriate to this war time. In addition to the foregoing, there are numerous other commodities in the nature of luxuries which might similarly constitute a means of increasing national funds without affecting, at least, the "cost of living."



The constitution of industrial enterprise is largely departmental—"Spokes in a Wheel." This series has for its object the featuring of, in racy, interesting and instructive fashion, the training, experience and achievement of those who to-day are transmitting effectively, energy in a variety capacity as "Spokes in the Wheels" of steam, electrical and hydraulic and refrigeration engineering.

WILLIAM MARTIN McROBERT

AT a time like the present, when surmises regarding future conditions are being made on all sides, and the probability of intensified competition looms up as a result of Britain's industrial awakening, it is reassuring, to those solicitous of Canada's future, to know that a prominent feature of the rising generation of engineers is the large number who, by birth, ancestry, or educational experience, have been able to absorb to a large degree those characteristics of the British race which, in view of future possibilities, may afford apt illustration of "diamond cut diamond."

A prominent English engineer, with world-wide experience, once remarked that Scotland was all right for breeding men, but was no use for feeding them. There may or may not be any truth in the latter part of the statement, but many of our readers who are acquainted with William Martin McRobert, sales engineer of the Galt Foundry Co., Galt, Ont., will be in perfect agreement that a deal of truth is contained in the first part of the remark.

Mr. McRobert is a native born Canadian, having first gazed upon the maple leaf in the immediate environs of London, Ont., in the year 1876. When three years of age his parents returned to their native land and settled in Aberdeen, Where our "Spoke" spent his early years, his education being received at Aberdeen Grammar School and Gordon's College. That he had early absorbed a due share of that determination and tenacity which are so authentically attributed to residents of the "Granite City" was evidenced by his decision to go through the mill as an apprentice engineer.

Much has been written and said regarding the value of experience in the eyes of Scotch people, and a recital of apprenticeship conditions under which our friend gained his knowledge of wheels and things may account in some measure for this trait. Commencing early in his teens, he started work at 6 a.m., quitting at 5.30 p.m., with two stops for breakfast and dinner. The remuneration offered seems to have been in inverse ratio to the hours worked when judged by Canadian standards. For instance, we are informed that the young apprentice was rewarded with the sum of 75c per week the first year, with annual increments of 25c per week up to the sixth year. Technical education was obtained through evening studies at the local Technical School over a period of four years.

WILLIAM MARTIN McROBERT

These conditions easily made it a case of the survival of the fittest, a further test of tenacity being the necessity of making up all lost time as double hours before the youthful journeyman received the coveted "lines," i.e. certificate of apprenticeship. Some certificate!

Dalgety Brothers, Aberdeen, was the firm where this training was undergone, and a short time afterwards our friend entered the service of the "P. and O." line of steamships, climbing through the various grades to the rank of service engineer, for which it was necessary to pass the Board of Trade examination for first-class engineer. A decade spent on ocean mail steamers familiarized Mr. McRobert with the operation and upkeep of power plant equipment to a degree seldom obtaining in land installations. The necessity for avoiding breakdowns at all costs, and the limited facilities for effecting repairs in case of accident developed an alertness and self-reliance which is typical of the modern marine man. It is not surprising, therefore, that when, after ten years of sea life, our "Spoke" decided to settle in the land of his birth, he was appointed chief engineer of the Canada Foundry Co., Toronto, a position which he held for three years before transferring his services to Gunns, Ltd., Toronto, in a similar capacity, but with the additional duties of master mechanic.

As sales engineer for the Galt Foundry Co., Mr. McRobert finds ample opportunity for drawing on his wide experience, his energies being devoted to the development of the Galt sprinkler stoker and the McNaughton grate bar. No combination of circumstances is likely to offer very great difficulty in the application of his personally acquired knowledge of things mechanical. In the course of his travels Mr. McRobert has had frequent opportunity of studying industrial practice in nearly every civilized country, having, with the exception of Northern Europe and South America, visited every part of the globe. His travel record includes over 70 passages through the Suez Canal, and also coast to coast trips in Canada and United States.

Mr. McRobert's home life is centred in Toronto, where he resides at 92 Symington Avenue, his son being a student at Toronto Technical School preparatory to following a kindred career to that of his father. His experience in occasionally isolated situations gave Mr. McRobert more than ordinary opportunity for appreciating the value of technical study, in fact, he considers that for any engineer or mechanic having ambition to advance in his profession it is imperative that he should keep abreast of the times by combining with his practical knowledge the study of reliable engineering literature, also the reading of the many interesting and instructive articles appearing in the current issues of mechanical trade journals.

At a picture-house the other day a picture was shown entitled:

"As God Made It."

Immediately following the projection of the title on the screen came the flash:

"Approved by the Board of Censors."

The Operators' Point of View

CALCULATING THE WEIGHT OF A FLYWHEEL

By D. A. Hampson.

THE weight of a flywheel needed for a machine which does all of its "work" during only a portion of its cycle can be determined by well-known formulae if certain assumptions are made and if the work can be expressed in foot-pounds. The most familiar machines requiring flywheels to balance work of this sort are punches and presses for sheet metal working. With these the work is done during a portion—say from one-tenth to one-half of the downward stroke; the remainder and all of the upward or return stroke are idle movements, simply overcoming the friction of the machine. As the belt is constantly running, it is the function of the flywheel to store up enough energy during the idle portion to overcome the resistance of the working portion of each revolution.

The first step in the calculations is to put that resistance in terms of foot-pounds; then to find just what is the proportion of idle to useful time. This is usually a matter of measurement and is reduced to degrees about the flyweel centre, for instance—20 degrees working, 340 degrees idle. If the number of revolutions per minute of the flywheel is known, this is again reduced and expressed as "seconds working," "seconds idle." If the speed is not known, one must be assumed for calculating purposes.

There must also be known, or assumed, the reduction in speed which the flywheel makes during the working period. This is an important factor and in the case of a new machine must be assumed, basing the assumption on experience and judgment—it is commonly stated as "per cent. loss in speed while actually cutting." In the case of cutting, say a thin sheet of brass the loss will be perhaps only 5 per cent. or less; if the length of the cut in the direction of the stroke is considerable, the loss may run high, perhaps 25 per cent.

Example of Application

Paper cutting machines are fine examples of the case where the length of the cut is a major part of the stroke. The vertical travel of the cutting knife may be 5 in. and for this size of machine the capacity would be at least 4½ in. of paper. This is many times the proportion found in machines for stamping sheet metal and furnishes a very interesting example for flywheel design. It is obvious that either a very heavy flywheel must be provided or else there will be a big reduction in speed when cutting, for if the wheel is not heavy enough, the machine will run slower and slower as the knife cuts downward and may even stop if the flywheel cannot give up energy enough to carry past the lowest point. A special paper cutter, built on much the same lines as an open side punch press, furnished a problem which the following calculations successfully solved: The data determined and assumed were as follows:—

1,050 lbs. pressure required back of the knife to do the cutting.

3 in.=stroke of press.

2 in.=1/6 ft.=length of cut in direction of stroke.

60 rev. per min.=60 cutting strokes per min.

Cut=110 deg. or .3 sec., idle=250 deg. or .7 sec.

18 in.=1½ ft.=mean diameter of flywheel rim.

Total energy required for the cutting stroke=1050÷6=175 ft. lbs.

The following formulae are now applied.

$$(1)\ \text{H. P.} = \frac{\text{ft. lbs. reqd.} \times \text{rev. per mm.}}{33{,}000} = \frac{175 \times 60}{33{,}000} = 32.$$

$$(2).\ E_1 = \text{ft. lbs. reqd.} \times \left(1 - \frac{\text{sec. of actual cut}}{\text{total time of stroke}}\right) = 175\left(1 - \frac{.3}{1}\right) = 122\tfrac{1}{2}\ \text{ft. lbs.}$$

$$(3).\ \text{Wt.} = \frac{E_1}{\text{constant} \times \text{dia.}^2 \times \text{rev. per min'}} = \frac{122\tfrac{1}{2}}{.0000118 \times 1.5^2 \times 60^2} = 1281.$$

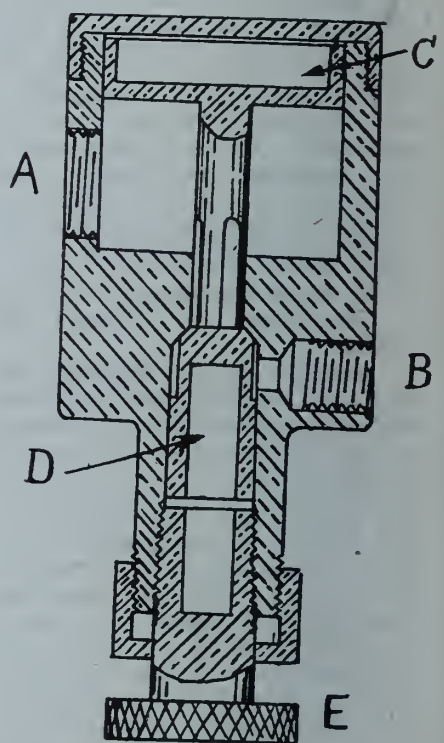
The constant in the denominator of (3) varies from .000002 for 2¼ per cent. loss to 000015 for 20 per cent. loss.

Formula (1) is not necessary to the flywheel calculation but gives an idea of the work to be done and the sizes of belt or motor needed. After the weight is found, the section of the rim necessary is a matter of adjusting width and thickness to other conditions. The entire calculation is free from complication and answers for all simple cases.

ADAPTING GASOLINE ENGINES TO BURN KEROSENE

By H. P. Hoag

AS THE price of gasoline advances the interest in the cheaper fuels for the gas engine increases and some experiences the writer had in adapting a line of standard gasoline engines to burn kerosene and naptha may be timely. The experiments covered a period of nearly two years before the following points were finally settled on. 1st: It was found that heating the air entering the carburetor reduced the power of the



AUTOMATIC WATER VALVE.

engine to a very marked degree. 2nd: To give best results, kerosene and naptha should be heated nearly to the evaporating point before passing the spray nozzle. 3rd: Water must be admitted into the carburetor with the fuel to retard the burning and give smooth running.

Heating the air was advocated by a number of writers but it was found after trying out many hot air devices, some home made and others from abroad, that in every case the power of the engine dropped, in some instances to but 70 per cent. that of gasoline, so that the hot air idea had to be abandoned altogether, as the manufacturer could

not send engines out that would not develop their rated power no matter how well the oil was burned.

Fuel Heated

Heating the oil was accomplished by providing a separate chamber around the outside of the fuel reservoir in the carburetor through which water is circulated, this water being taken from the hottest part of the cylinder jacket. By this means the fuel is kept at the proper temperature and is warm enough by the time the engine is ready to turn on the kerosene; gasoline is used to start with.

Spraying water into the mixture gave a good deal of trouble, that is to get the proper amount for each charge, because when using a throttle governor it became evident that a fixed amount of water for each charge was not the thing, but that the quantity of water should vary according to the load or the amount of fuel taken in. Some means to automatically prevent water running into the cylinder when the engine was shut down was also required, as the operator could not be depended on to turn water off each time.

Use of Automatic Valve

To embody the above requirement the automatic water valve shown herewith was designed, the construction being as follows. In the upper chamber of the valve body there is an air piston C which extends down onto the small inverted valve D. The valve being held up to place by a light spring (not shown) placed inside the valve and the hollow adjusting screw. The opening A is piped into the carburetor between the spray nozzle and the throttle valve. Opening B is piped to a convenient place in the water jacket with a stop cock in the line for shutting off the water when using gasoline. The action is as follows, (the upper chamber being in communication with the carburetor): when suction takes place the piston C is drawn down against valve D, forcing it away from its seat by a varying amount according to the load on the engine, when the necessary amount of water flows past the valve D then the pipe from A into the carburetor entering the cylinder with the fuel. It will be noticed there is a fine threaded adjusting screw provided at the bottom to set the stroke of valve D to suit the size of the engine. It is obvious that with this device the quantity of water is varied according to the load also that no water can get past valve D into the cylinder when the engine is not running. With this arrangement it was found not only did kerosene burn(in the ordinary gas engine) as well as gasoline but usually eight per cent. more power was developed with the cheaper fuel.

DOESN'T BELIEVE IN SAVING TIME.

By N. G. Near.

BOILER factory owners still exist who think they have sound arguments against good time-saving devices. They believe in the old idea—plenty of "elbow grease" as they called it. They think it laziness to permit the brain to do the work through coal and machinery.

I met a friend salesman the other day who told me about an argument he had with such an owner of a boiler factory. He had tried to sell the owner an up-to-date, time-saving machine, but the owner said, "If we used every time-saving device in the world in this factory we wouldn't have anything more to do." Although it is usually fatal for a salesman to be sarcastic with a prospective buyer, this friend of mine said, "Your're right. Henry Ford believes in using as much time-saving machinery as possible in his automobile factory, and that is why he hasn't anything to do now-a-days."

It's a fact that some so-called time-saving machines are actually time-losers and they should be carefully weeded out. Again, the time-saving machine may be a time-saver only where it can do jobs over and over, and where it can be kept everlastingly at it. In many instances, holes can be drilled in certain pieces by hand more quickly and more economically than by machinery, and such machinery may be the so-termed "time-saving" variety.

If TIME was MONEY in Ben Franklin's day, doesn't it seem reasonable that time is worth MORE money now?

OVERCOMING TROUBLE WITH STEAM PIPE

By J. James.

IN your April issue, H. Westwood has something to say against the use of a receiver on a steam line. No doubt he is right if a continual increase in the quantity of steam required is needed; however, the scheme worked out on the steam line, as described in the January 1917 issue. According to theory, the idea is wrong, but Mr. Westwood apparently overlooked the statement that the scheme was tried out with success. All the figures and theory in the world will not change facts. Perhaps the engine required such a small quantity of extra steam that the slight reduction in friction and the separator effect of the receiver "did the trick." No doubt, if it had been allowable, the pressure in the boiler could have been raised a few pounds, and the use of the separator receiver dispensed with.

In 35 years' experience I have seen theory proved wrong more than once. What appeared impossible on paper would prove quite possible when tried out by some fellow who had very little experience as an engineer. Of course, we all know that such cases are the exception and not the rule, but there are exceptions.

Right in the plant where I am employed, there is an outfit connected that would make some engineers open their eyes in wonder. A 10 x 12 x 14 in. compound steam pump delivering 160,000 gallons of water every 24 hours, an 8 x 10 in. steam engine making 260 rev. per min., and a 5 x 6 x 8 in. steam sewage pump, have their exhaust pipes connected into one 2½ in. pipe. This pipe delivers the exhaust steam into a heating main 100 feet distant from the engine, and the pumps are 35 feet further along the line. The back pressure never exceeds 5 pounds and often not 2 pounds. Figure it out. The exhaust outlet on the large pump and the engine is 3 inch, the small pump 1½ inch. The steam main to the engine and compound pump is 2½ inches each, the small pump 1 in. Steam pressure 110 lbs. per sq. in. absolute. This is no job that was in existence in the dim and misty past; it is doing business at the time of writing and likely to be so doing for some years to come.

All we old stagers could tell about different schemes worked out on paper failing to work out in practice, and we have often been surprised to find what we considered impossible in practice was not so in fact. Without theory, steam engineering would be a very dull study, indeed, but theory is not perfection in itself.

I have figured on some house heating jobs, allowing so many feet of radiator surface, according to rule, per 100 feet of space, allowing for doors, windows, north and south walls, etc., etc., and some other fellow who did not place absolute trust in theory alone, but used judgment and common sense, would take the job away from me at a lower price, putting in about a third less radiation. I had figured on an abundance of heat at the lowest outside temperature to heat the house properly. Another case of theory gone wrong.

I have taken several courses of correspondence study and hold diplomas for same; I have first class papers from the old Ontario Association of Stationary Engineering, which quit in 1907, but I do not believe in sticking to theory, right or wrong. Experiment, try things out—it will often pay if the try out will not cost too much.

And, lastly, the receiver was not 8 feet in diameter; it was less than three feet, which, according to theory, looks worse than ever.

CYLINDER IRON

By T. J.

IF an examination be made of the surface of a cast-iron cylinder liner which has been some time in use, it will be found to be pitted with small holes. This is generally supposed to be due to the flaking off, or wearing away, of the soft graphite plates which lie between the harder grains in coarse grained cast-iron; but, as Mr. J. E. Hurst has recently pointed out, microscopical investigation suggests that this is only half the explanation. It appears that the wearing down of the inter-granular graphite is only a preliminary stage in the formation of the actual depressions seen with the naked eye on the worn surface.

What happens is that a certain amount of soft material is in the first place, detached, and some slight surface disin-

tegration caused under the abraiding action of the piston rings. Some of this detached material becomes powdered and suspended in the film of oil, and acts still further upon the surface until the softer portions are worn a little lower, and the harder grains project above the surrounding material, becoming still harder as a result of the polishing action of the piston rings. Eventually some of these projections are loosened and break away from their groundwork, leaving hollow places behind them. These are the holes which show themselves on the surface of the liner that has been some time in use, and this appears to be the mechanism of surface disintegration in engine cylinders. The glazing of the hard grains in cast-iron, which is subject to a rubbing action, is thus the cause of the anti-frictional properties of cast-iron, and is at the same time the cause of such disintegration as takes place.

The hard glaze which a cast-iron liner takes after a period of running is a matter of common experience. The surface of a high speed engine cylinder becomes, with length of service, increasingly difficult to file, and the raised markings left on the cylinder walls after a "seizure" has taken place are often glass hard, and cannot be filed at all. Mr. Hurst suggests that the most important cause among the many responsible for the glazing of the surface of cast-iron is that, under the alternating stresses brought about by the motion of the piston, the surface grains are deformed by being broken down along the slip planes, ultimately producing a surface of very fine crystal structure. Micro-examination of such surfaces reveals in many instances, very fine granular structures, even at high magnifications. Such surfaces are harder, and will obviously be far less sensitive to the effects of surface disintegration than the original coarser grained structure.

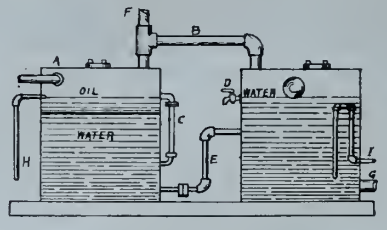
If this interpretation be correct, it provides a good theoretical justification for the practice, which it is believed some continental gas-engine makers follow, of running pistons in their cylinders for some time under the belt before putting the engine to work on load and under its own power. It would be interesting to inquire how much there is in common between the glazing phenomenon in cost-iron and the great toughening of the surface of manganese steel, which takes place under a rolling or hammering action.

AN OIL SEPARATOR

By J. E. N.

GREAT damage has been caused by allowing oil to get into steam boilers. Separators are placed upon the exhaust pipes from pumps or engines, a trap connected to the drip from the separator, and the engineer often proceeds to forget all about oil in his returns when the job is completed, with the result that the trap becomes inoperative from thick cylinder oil, and if nothing more serious happens, the result is that the boiler cleaner will find a long dirty job to be done the next time the boilers are opened for cleaning. However, it is quite possible that damage may be caused by a foaming boiler, or a burned or bagged plate is a possibility.

In the sketch shown is an idea worked out and said to give good results. Two iron tanks are secured, and the exhaust inlet enters at A. The pipe B connects



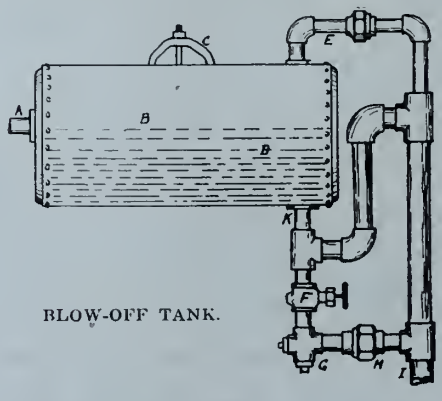
OIL SEPARATOR.

the two tanks, the branch F being open to the atmosphere. Suitable plates are bolted to the top and side of each tank, and can be removed to clean out the tanks. C is an ordinary gauge glass, which shows the depth of oil in the tank; a small quantity of water can be drawn off at D every few days to show if any oil is getting into the draw-off tank; the clean water suction is shown at G. Pipe H is the overflow oil pipe to either a receiver or the sewer. The water passes from the receiving tank to the discharging tank through the pipe E. Clean city water can be run into the tanks at any time desired through the piep I. An improvement would be made if an ordinary float operated valve was connected to the pipe I, as shown.

BLOW-OFF TANK

By John Port.

THE connections on the blow-off tank, illustrated herewith, are different from those generally used. The blow-off pipe A from the boiler is 2 in. in diameter. The outlet pipe K is 3½ in., the valve and connections at F, G and H are 2 in., also the pipe E is 2 in. At C is a clean-



BLOW-OFF TANK.

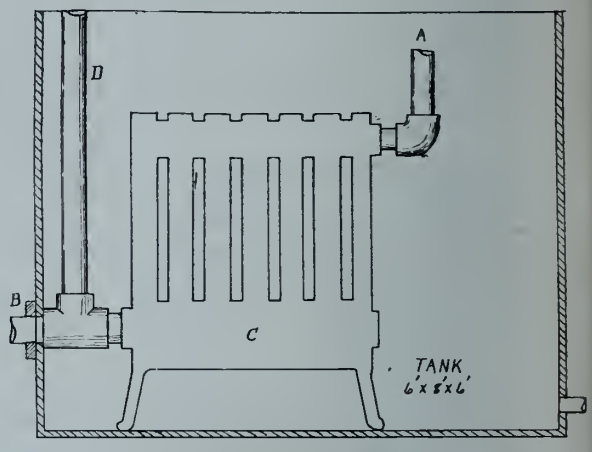
out hole. Should the trap at K become stopped up there will be an opening through E. The valve F can be opened once in a while, and the dirt, which may settle in the inlet end of the tank, washed out.

The tank should be about 30 x 60 inches. Note that the inlet pipe is just above the outlet of the trap water level. The end I runs to the sewer.

DOMESTIC WATER HEATER

By John Ellethorn.

A FACTORY which used considerable hot water for employees' meals, etc., employed a novel arrangement for heating the water. Originally they had a pipe coil along the bottom of the tank running the exhaust, from a small upright steam engine, through it. A number of small holes developed in the coil, and it had to be discarded. An old Bundy cast iron radiator, which was not in use, was connected in the open tank, as shown in sketch. The inlet was at A, and the out-



DOMESTIC WATER HEATER.

let to the hot well was through a valve at B. Sometimes the water was not as hot as required, so as an experiment the pipe D was added. This pipe extended over the top of the tank, and was connected to the outlet pipe beyond the valve at B. The idea was that some back pressure would be necessary to keep the radiator free of condensation with valve B closed, thus getting a greater number of heat units through the radiator into the water. An oil separator was attached to the exhaust, and the clean condensate returned to the hot well.

The tank was cast iron, and had a properly constructed cover. However, the manhole cover was not fastened.

The water level was regulated by a ball cock in the usual way.

The radiator was a large one, and gave excellent results.

Some Loan.—A Kerry peasant sued another for a loan. "It was a Kathleen Mavourneen loan, yer honor, an Paddy Kane knew it was at the time he gave it to me," said the defendant.

"A Kathleen Mavourneen loan?" said the puzzled judge. "What sort of a loan is that?"

"That's what we call one kind of loan, yer honor, down in our part of the country; it may be for years and it may be forever."

Question and Answer Section

Question.—I have a D.C. motor, 1-6 horse-power, 110 volts, which it is desired to use on a 220 volt circuit. What method would you suggest that it could be used and would it apply to alternating current?—J.B.

Answer. — The most satisfactory method would be to purchase a small transformer. If the motor is of the type which runs on either D.C. or A.C., it would be quite satisfactory. Otherwise it would be necessary to get another motor as the cost of rewinding, etc., for the higher voltage and different current would not be justified by circumstances.

* * *

Question.—Is there any necessity for having a damper in chimney which gives far more draft than required. The chimney is connected to a battery of boilers and there is at present a damper between the boiler and smoke box of each boiler.— F.C.

Answer.—The individual dampers at each boiler are necessary to take care of any variations in their conditions such as class of fuel, rate of working, etc., while the main damper in the chimney is required to counterbalance variations in weather conditions which affect the draft of the boilers as a whole.

* * *

Question.—What is the difference between a pop safety valve and an ordinary spring loaded valve. Are there certain conditions which make it more desirable to use a pope valve?—T. K.

Answer.—Pop safety valves are now universally used in marine work and other lines where the working pressures are high and there is little margin between the working pressure and the blow off point. They are so constructed that when slightly lifted off the seat, an additional area is exposed to the pressure of the steam, with the result that the valve is kept open until the boiler pressure has dropped well below that at which it opened. In this way the valve is not exposed to the cutting action of the steam which takes place when a valve is simply showing a feather of steam, resulting in longer life to the valve. Ordinary types of valves are more suitable for plants where the working pressure seldom approaches the blow-off point, thus acting as safety valves pure and simple and not so much as pressure regulators.

Question.—Although I have had occasional work to do in connection with ammonia refrigerating plants, I have never been in any accident where I received damage or injury by the ammonia. As I may not always be so fortunate, I often wonder just how I should act in case of accident?—R. L.

Answer.—As an operator of some experience it is presumed that you know what to do in the way of manipulating the plant, and that your inquiry relates more to method of treatment, etc. In this, as in any emergency one must be governed by circumstances. If you are overcome by the ammonia fumes your actions will be of a very limited nature, and help from another will be required. It is a good plan to have a supply of pure cider vinegar on hand, diluted to a point where you can drink it; acetic acid which is the active agent in this neutralizes the ammonia, which is not the case with ordinary commercial vinegar having sulphuric acid as a base.

In the case of a serious leak which it is required to repair, a helmet of any type as supplied for the purpose should be on hand and instantly available, failing which a number of cider-soaked sponges may be tied around the nose and mouth although these do not protect the eyes. A weak solution of boracic acid in water should be used for bathing the eyes while equal parts of raw linseed oil and lime water make a splendid dressing for flesh burns.

* * *

Question.—What is the formula for finding the horse-power of a given tangential water wheel as the water pressure is decreased or increased?—J. M.

Answer.—In order to determine the amount of power available from a given quantity of water under a given head, multiply the number of cubic feet of water per minute by the number of feet of head, and this by 62.3, which equals the weight of one cubic foot of water. Divide the result by 33,000, which equals the number of foot-pounds in one horse-power, and the result is the theoretical horse-power in the water. This should be multiplied by the percentage of efficiency, which you can take as a rule as 80, which will give the horse-power available on the water wheel shaft.

C. A. S. E. CONVENTION AND SUPPLIES EXHIBITION

THE following provisional programme has been arranged for the annual convention of the Canadian Association of Stationary Engineers and Supplies Exhibition, to be held at Toronto from July 24 to 27, inclusive. Premises have been rented at 70 King St. West. The exhibitors will occupy the ground floor, while the first floor will be used for the convention sessions. It has been decided to keep the exhibition open each day, excluding Wednesday, July 25, which has been set apart for a trip to Niagara Falls, via Lake Ontario.

Tuesday, 24th.

Convention opening by a member of the Board of Control. Smoker in the evening—boxing and music. Entertainments and outings for visiting ladies.

Wednesday, 25th.

Engineers and exhibitors' day trip to Niagara Falls, boat to Lewiston, and trolley via the Gorge route to Niagara Falls, N.Y. Lunch there and return on Canadian side by trolley, to Queenston Heights, and back to Toronto by boat.

Thursday, 26th.

At 10 a.m., annual meeting of Exhibitors' Association. C. A. S. E. sessions. In the evening there will be an automobile trip round the city and then to Scarboro Beach Park.

Friday, 27th.

Closing day. No special feature arranged as yet.

The Exhibitors' Association executive this year is as follows:—Hon. President, H. P. Stevens; Past President, H. L. Peiler; President, Earl F. Hetherington; 1st Vice-president, Lloyd Archibald; 2nd Vice-President, C. N. Schragg; Treasurer, B. G. Newton; Secretary, Gordon Keith; Asst. Secretary, L. H. Rumage; Chairman Exhibit Committee, James E. Fiddes; Entertainment Committee, A. W. Crouch; Reception Committee, H. T. Ramshaw.

CANADIAN ELECTRICAL ASSOCIATION

AT a meeting of the Managing Committee of the Canadian Electrical Association, held in Ottawa, on April 26, it was resolved that the association hold a strictly business two-day convention on June 7 and 8, in Montreal; that no fund or provision be made for the entertainment of delegates, but that arrangements be perfected for full reports from the various technical and commercial committees

of the association, these reports to be distributed in advance and discussed at the convention; that the meeting be made as practical and businesslike as possible, with a view not only of stimulating membership, but so as to be of the greatest assistance possible to those attending. In connection with the above:—

The Managing Committee feels that the time is ripe for a meeting of the above character.

Many developments have taken place in the electrical world since they have had an opportunity to discuss these matters.

No diversion is contemplated, and attendance is asked in the interest not only of one's own affairs, but also of the industry at large.

The National Electric Light Association has given up the idea of its usual type of convention for this year.

Under the circumstances, the association is not making any special arrangement either for accommodation or transportation. These are matters which each delegate will settle for himself.

Place of meeting will be the Ritz-Carlton Hotel, and arrangements will be made so that, on the evening of June 7, all may dine together at a set rate for each person.

GRAND LODGE, C. A. S. E. INCORPORATION

AN Act to incorporate the Grand Lodge of the Canadian Association of Stationary Engineers which has been before the Federal Government at Ottawa, is now effective, passage of the articles of incorporation having received the consent of both the House of Commons and the Senate. . Needless to say with completion of the procedure involved, an added stability, enlarged scope, and therefore greater degree of usefulness may be expected to mark the future activities of the association. The Articles of Incorporation follow:—

Whereas the persons hereinafter named have by their petition prayed that it be enacted as hereinafter set forth, and it is expedient to grant the prayer of the said petition: Therefore, His Majesty, by and with the advice and consent of the Senate and House of Commons of Canada, enacts as follows:—

1. Robert Dyson, of the city of Guelph; John Hale and Alfred W. Heath, both of the city of Hamilton; Rodger F. Gofton, of the city of Kitchener; William Cooke, of the city of Belleville; John W. Beasley, of the city of Chatham, all in the Province of Ontario; and William G. Forbes, of the city of Montreal, in the Province of Quebec, practising stationary engineers, together with such other persons as may become members of the association, are hereby incorporated under the name of "The Grand Lodge of the Canadian Association of Stationary Engineers of the Dominion of Canada," hereinafter caller "the Association."

2. The persons names in section one of this Act shall be the executive officers of the Association and shall hold office until their successors are elected.

3. The head office of the Association shall be in the city of Hamilton, in the Province of Ontario.

4. The affairs and business of the Association shall be managed by a representative body to be known as "The Grand Lodge," consisting of not less than seven nor more than fifteen members, who shall be elected annually in such manner as is determined by by-law of the Association.

5. The executive officers, and such officers as are designated by the by-laws of the Association, shall be elected from delegates to Grand Lodge convention.

6. Subject to the constitution and by-laws of the Association, branches under the name of "Lodges," subordinate to the Grand Lodge of the Association, may be established in Canada under the title or number designated in the charter granted by the Grand Lodge of the Association when constituting such branches with such powers as the Association may determine by by-law: Provided, however, that such powers shall not be in excess of those conferred on the Association by this Act.

7. The Association may make such rules and by-laws for the government and management of its business and affairs and for the guidance of its officers and members, and especially with respect to the qualification, classification, admission and expulsion of members, the fees and dues which it may deem advisable to impose, the control and management of its funds, the number of members composing the Grand Lodge, and the number, constitution, powers and duties of an executive committee, board of trustees or managing committee, and of its officers, and generally for regulating every matter, and thing proper and necessary to be done for the good of the Association and for the carrying out of the objects and purposes of this Act.

8. The objects and purposes of the Association shall be to promote by all lawful means the efficient operation of steam and electric power plants, and for the said purposes:

(a) To serve as a school of instruction for its members;

(b) To hold meetings for discussing theoretical and practical matters pertaining to its calling;

(c) To examine stationary engineers and firemen as to their proficiency, and to grant graded certificates of ability to its members, and to be a medium through which steam and electric users may be supplied with good and reliable engineers, and to grant relief to its members in cases of sickness and distress.

9. All members in good standing of existing institutes incorporated under provincial Acts, and of associations who apply for membership after the passing of this Act, and other persons of whose qualifications and fitness the Association approves, shall be eligible for membership in the Association.

10. The first general meeting of the Association shall be held during the year 1917, at such time and place and upon such notice as the executive officers of the Association may decide. Subsequent general meetings shall be held annually as the by-laws of the Association may provide.

11. At any general or special meeting, members may be represented and vote by proxy, but no such proxy shall be exercised by a person who is not a member of the Association and in good standing.

12. The Association may affiliate with any association or corporation having the same or similar objects.

13. Subject to provincial laws, the Association or any branch thereof may acquire by devise, bequest, purchase, gift or lease, real property, not exceeding in the aggregate of one hundred thousand dollars, and may sell, mortgage, lease or dispose thereof, but so that the Association shall apply all its profits,if any, or their income, in promoting its objects, and shall not at any time pay any dividends to its members; but the provisions of this section shall not prevent the remuneration of members of the Board of Directors, or officers of the Association for services rendered out of any surplus remaining after the ordinary expenses of the Association have been met. The Association shall, within ten years after its acquisition of any real estate, sell or otherwise dispose of and alienate so much thereof as is not required for the use and occupation of the Association.

14. If any subordinate lodge or member of the Association ceases for any cause whatever to be a member of the Association, it or he shall not, nor shall its or his representative have any claim against the funds and property of the Association.

15. The Association shall acquire and take over all existing business and rights held and enjoyed by and be subject to all the obligations and liabilities of the Canadian Association of Stationary Engineers, incorporated under the provisions of the Revised Statutes of Ontario, 1877, chapter one hundred and sixty-seven, An Act respecting Benevolent, Provident, and other Societies, and except in so far as it may be necessary for the purposes of such transfer, the powers and authority vested in the Association under the provisions of this Act shall not be exercised or become effective until all the business and rights held and enjoyed by the said the Canadian Association of Stationary Engineers have been transferred to the Association and evidence of such transfer satisfactory to the Secretary of State of Canada has been filed with the said Secretary of State.

First Guest (at reception)—Have you a speaking acquaintance with that lady in black?

Second Guest—No; I have a listening acquaintance with her. She has a speak-acquaintance with me.

First Guest—I don't understand.

Second Guest.—She's my wife.

OIL SEPARATORS—II

As pointed out in the previous article, gravity, impact and change of direction are employed either singly or collectively in all mechanical devices for separating oil and moisture from steam. The manner in which these

FIG. 7. "BUNDY" OIL SEPARATOR SHOWING METHOD OF REMOVING PLATES.

features are combined varies with the conditions under which the separator is to be used.

Bundy Separator

This separator is of the baffle type and employs a series of separating plates, one of which is shown in course of withdrawal in Fig. 7. Each integral column of the plate has a channel or direct cut through its centre, communicating with the cups or sub channels which are bored through from the front of the plate, and which are set to fall against the direction of the steam travel. The columns of the separator plates are arranged in staggered formation so that the steam in passing through the open space between the columns in any plate, will impinge upon a column in the succeeding plate.

All steam, therefore, in passing through the nest of plates must touch more than one; consequently the particles of oil and water, suspended in the steam, cling to the surfaces of the cast iron columns against which they are projected, collect in the anterior cups, enter the interior channel and fall into the receiver below. The flanges at the bottom of the plates, "make up" close, and prevent any portion of the water or oil being picked up by the steam and carried forward. As shown in the illustration, all of the plates can be removed from this separator for the purpose of cleaning without breaking any pipe connections. It is desirable to do this at intervals as the more solid particles of the oil adhere to the filter plates and do not drain freely to the well, A thorough boiling in potash or soda solution for several hours removes all traces of the most stubborn deposits.

This separator is built by the Canadian Griscom-Russell Co., Montreal, who also build the Stratton Jr. oil separator, a type which is well adapted for handling steam at high velocities.

Stratton Jr. Separator

This apparatus is specially designed to provide means of condensing the volatile gas in which form much of the oil is carried over from the steam cylinder. The method adopted is to cause the entering steam to pass through a curtain of water thrown entirely across the throat of the separator by a spray nozzle located in the centre of the inlet steam passage. This spray forms a zone across the pipe in which the temperature is reduced, thereby condensing the oil gas which is in very unstable equilibrium; and as this condensing action occurs in contact with water, the oil gas, as it condenses, collects around the individual particles of spray water, which, coming in contact with the liquid oil in the steam completes the process of oil collection. The resultant oil-covered drops of water are then carried by the current of steam into the body of the separator which is

FIG. 8. "NATIONAL" OIL SEPARATOR SHOWING INTERNAL RIBBED BAFFLE WITH SUPPLEMENTARY PORTS.

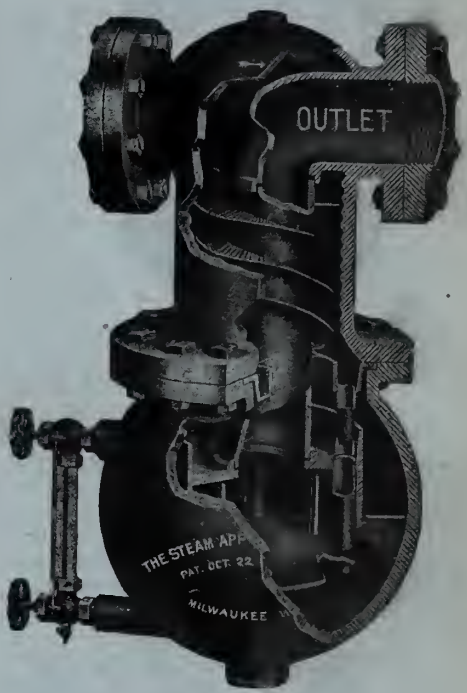


FIG. 9. SECTIONAL VIEW OF "TRIUMPH" OIL SEPARATOR. NOTE SPIRAL PASSAGE AND DRAIN TUBES

constructed on the centrifugal principle. Here the oily moisture is thrown to the walls of apparatus and effectively separated from the steam which leaves the separator through a central vertical pipe amply distant from the water and oil in the receiver space below.

National Separator

This device is of the horizontal type, see Fig. 8, and embodies all of the effective principles, both as to design and construction that insure separation of oil from exhaust steam. Gravity impact and change of direction are all employed to eliminate the oil from the steam, and properly disposed baffles prevent it being picked up and carried along.

The internal area of this separator is unsually large, thus allowing the velocity of the incoming steam to be reduced to a point where the heavier particles of foreign matter fall out of the current by gravity. Minute particles carried in the current of steam, impinge on a main baffle which extends the full width of the separator and has vertical ribs to pre-

vent side travel. Through this baffle is a series of ports or holes each of which is provided with an individual baffle so disposed that the steam must make a further change in direction in order to pass through. The lower part of the

FIG. 10. "VICTOR" OIL SEPARATOR WITH ALTERNATE VERTICAL GROOVED BAFFLES.

separator forms a storage chamber from which a large drip opening allows drainage to be removed.

This apparatus is a product of the National Pipe Bending Co., Newhaven, Conn., and is built in regular sizes from 3 in. to 24 in.

Triumph Separator

This separator, along with the Victor which follows, is built by the Steam Appliance Co., Milwaukee, and makes prominent use of the centrifugal principle. The entering steam is led downward by a series of spiral baffles which cause the oil and heavy particles of entrained moisture to be thrown outward against the walls of the body. These walls are corrugated to assist in the

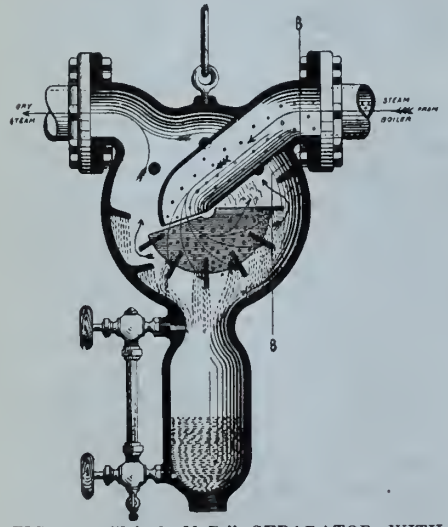

FIG. 11. "W & McD." SEPARATOR WITH RADIAL BAFFLES.

deposition of the oil particles, and the spiral baffles do not touch the walls, so that collected matter drains down into an annular catch basin or trough from which they are conveyed to the bottom of the receiving space. The steam makes its exit through a central vertical pipe to the outlet as shown in illustration, Fig. 9.

Victor Separator

A curved corrugated baffle is the feature of this separator which is of the horizontal type and adapted for use either as a steam or oil separator. Sectional view, Fig. 10, shows the disposition of the curved baffle opposite the inlet on the right, which is followed by two succeeding straight baffles on either side. The entering steam is effectively broken up by the curved baffle, the entrained oil and moisture being precipitated, after which the steam passes around the outer ends and impinges on the straight baffles shown. The lower portion of the vessel has ample capacity as a storage chamber.

W. & McD. Separator

The horizontal type of separator shown in Fig. 11 is built by Watson & McDaniel Co., Philadelphia, and combines reduced velocity with change of direction. Several plates are disposed radially around the inner end of the inlet pipe so as to offer little if any resistance to the passage of steam, while their surfaces are such that oil deposited thereon is gradually washed over by the action of the steam and finally drops clear of the current into receiver.

ascending or descending currents the separating elements being arranged certically with the drainage space toward the left for connection to grease trap. An access door on the side permits withdrawal of the plates for cleaning. The horizontal type has the plates so arranged that they can be taken out as a

FIG. 13. HORIZONTAL "SWARTWOUT" OIL SEPARATOR EMBODYING HELICO-CENTRIFUGAL PRINCIPLE OF OPERATION.

unit by removing the lower part of the casting which forms the receiver space. The curved shape of the baffle plates is clearly shown, also retaining springs

FIG. 12.
LEFT.—VERTICAL TYPE WARREN OIL SEPARATOR.
RIGHT.—HORIZONTAL TYPE OF SAME APPARATUS.

Webster Separator

Two types of this oil separator are shown in Fig. 12, that to the left being the vertical design, and that to the right the horizontal. These separators are equipped with steel multi-baffles, formed of a number of hooked steel plates interposed to the flow of the steam, causing separation by impact, by change of direction, and by adhesion. There is no unobstructed path through any of these oil separators, yet the free area through which steam must pass is several times greater than the area of the connections thus minimizing pressure loss due to friction.

The vertical type is suited for either

above which hold the unit in place. Darling Brothers, Montreal, build and market the various sizes of this apparatus.

Swartwout Separator

These oil separators are of the helico-centrifugal type relying entirely upon the correct application of centrifugal force to obtain the desired separation of oil particles from the steam. Where proper lubrication is employed, the oil is never evaporated at ordinary steam pressures, but is merely mechanically mixed with exhaust steam and hence is readily susceptible to the influence of centrifugal force. Figs. 13 illustrates the horizontal type of this device. A helix

of twisted plate is inserted in the inlet passage in such a way that the mixture of steam and oil is caused to travel around the passage, causing centrifugal force to come into play, the full effect of which is obtained when the steam reaches the enlarged portion of the casting. Here the particles of oil and associated water are thrown far beyond the limit of the moving column of steam which because of its excessive lightness is scarcely affected by centrifugal force.

The steam passes out through an opening with a tubular extension which prevents the separated particles from escaping with the steam. Ample capacity is provided in the reservoir for separated matter. The Ohio Blower Co., Cleveland, O., are the builders of this separation which is made in a full range of sizes from 1½ in. to 40 in.

LIFT AND FORCE PUMPS

IT is a well-known fact that, under the class of pumps styled "the lift and force type," are included those of the bucket-and-plunger class, but it is not so generally remembered that a bucket-and-plunger pump is double-acting. If one examines a bucket-and-plunger pump, it will be seen that it is a combination of a bucket pump and a plunger (or ram) pump. In general terms the diameter of the ram (of plunger) should be one-half of the area of the bucket attached to the end of the ram. Its action is as follows:—

When the bucket is raised, a column of water equal to the bucket displacement follows it, the length of such column being precisely equal to the length of the stroke of the pump. At the return stroke, and when the bucket is progressing downwards, i.e., towards the foot valve fixed in the body or chamber of the pump, the water passes through the combined area of the passages through the bucket, lifts the bucket valve (or valves), and accumulates above the bucket. Now, the ram, being one-half of the area of the bucket, leaves an annular space around the ram equal to half of the area of the entire area below the bucket. So it follows that half of the quantity of the water that has passed the foot valve, and has passed through the valves of the bucket, is raised up the main, the other remaining in the barrel above the bucket. When the bucket again moves upward, the remaining half of the water belonging to that particular stroke (or cycle) is lifted into the delivery main. From this it will be clearly understood that half of the quantity of water is delivered to the main on the up stroke and a half on the down stroke. Consequently the pump is purely double-acting, but delivers only the same quantity of water per full cycle, or stroke, as a single-acting pump of the same diameter of barrel .

In designing such a pump, careful note should be made that the passages through the bucket are of ample area, the webs of the bucket as thin as reasonably possible, and well tapered, and having the thinnest edge of the webs towards the foot valve. The junction between the plunger and the bucket should be so designed that ample water way is given for the passage of the water through the bucket valve, the orthodox and accepted means of accomplishing this being the well tapering of the bottom end of the plunger where it joins the bucket.—Practical Engineer.

GRAPHITE LUBRICATION FOR CYLINDERS

By M. Meredith.

THERE are many purposes for which exhaust steam could be used with very great advantage were it not for the lubricating oil which becomes suspended in it as it passes through the cylinder. Many attempts have been made to find an alternative lubricant to oil which, while answering the same primary purpose, will be free from its many disadvantages. Naturally, attention has been turned to graphite, which has been proved to have excellent lubricating qualities for many kinds of work. Pure graphite, in the finest powder form, has for many years been available, and there have not been lacking efforts to use it for cylinder lubrication; but with little success, for it was soon found that the graphite was apt to accumulate behind the piston rings, in the ports and pipeways, and even in the condensers, to such a degree that the working parts became clogged and the passages choked. For these reasons the attempt to use powder graphite for cylinders was abandoned.

Late in 1906, however, Dr. Acheson, in the United States, discovered the "deflocculation" process, whereby the particles of graphite in its powder form, already fine enough to pass through a sieve having 40,000 meshes per square inch, are further broken down so that each particle is subdivided into about 1,000 parts. These particles are so small that they will pass through the finest chemical filter paper almost as readily as pure water, and are too fine even to be rendered visible by a sunbeam when floating in air.

E. W. Johnston recently gave an account of the successful use of this ultra-fine form of graphite for cylinder lubrication to the Birmingham Association of Mechanical Engineers. Searching some six years ago for some means of economically overcoming the difficulty of oil contamination in the feed water, and particularly in the exhaust steam, he determined to try the deflocculated graphite. Having overcome the difficulty of securing a continuous and adjustable sight-feed by using a U shaped sight tube filled with paraffin instead of water, placing the feed nozzle at the top instead of the bottom, and passing the water-borne lubricant into the current of steam he applied the graphite to the cylinders of three 50 kw. high speed dynamo engines, two deep borehole pumping engines, and certain other steam pumps operating on saturated steam at 120 lbs. pressure. No trouble was experienced and the usual three weekly inspections of cylinders showed that the general impression of efficient lubrication was well founded.

One of the high-speed engines, after accurate gauging of the valves and cylinders, was put on a six months' running test. At the end of this period the greatest wear at any point was found not to exceed one-thousandth of an inch, and it was particularly noticed that the walls of the high-pressure cylinder and piston rings were in faultless condition, having mirror-like surfaces. The implication was that the graphite lubricant had formed a real graphite coating on the rubbing surfaces, espcially as, in certain cylinders composed of more open-grained iron, the graphite had evened-up the minute depressions. Since uniformly satisfactory results were obtained also on the pumping engines and other auxiliaries, the use of oil was abandoned, and for the last five years the entire plant has been worked on this fine graphite as the sole cylinder lubricant, with the result that all available condensed steam can now be returned to the boilers, and 10 per cent. only of make-up water is added daily. The boilers are free from grease and entirely free from suspicion of "pitting," and a feed water of considerably higher temperature and exceptional purity is available, resulting in further fuel economy. Mr. Johnston makes it plain that his experience has only been in connection with engines running on non-superheated steam, as to the results that might be derived when operating with superheated steam, he is not in a position to express an opinion.

THE EFFECT OF STORAGE ON COAL

By S. D.

IT IS a matter of obvious and common knowledge that if stored coal be allowed to generate spontaneous heat its calorific value will suffer heavily, and for that reason storage under water has been from time to time advocated and practised; but there is also a widespread assumption that apart from spontaneous heating coal stored in the open deteriorates sensibly in the course of a year or two as a result of disintegration accompanied by chemical loss. Tests carried out over the last five years point to the entire fallaciousness of that belief, so far at any rate as the gas-making properties of coal are concerned.

A truck load of each of two grades of gas coal were set aside five years ago for the purpose of the experiment. The coal was stored in the open, in bins nine feet deep, provided with separate compartments, and each succeeding year a compartment was cleared and the coal tested in 400 lb. retorts. The results fluctuated somewhat from year to year, but after allowing for certain variables in the working of the retorts, the conclusion was arrived at that no deterioration in the gas-making quality of the coal had taken place even at the end of the fifth year.

The main body of the coal suffered little physical change during the five years. The top six inches had crumbled considerably but even in this top six inches chemical analysis failed to reveal any material change, even after five years' weathering.

Progress in New Equipment

AUTOMATIC TEMPERATURE CONTROL

THE demand for automatic apparatus wherever applicable has led to the development of automatic temperature controllers for gas and oil-fired and electrically-heated furnaces, a comprehensive line of these devices being now manufactured by the Bristol Co., Waterbury, Conn.

The principle on which these new devices are designed is to employ three elements—the measuring element, the contracting element, and the operating element.

The measuring element consists of various types of Bristol electric pyrometers and thermometers. The controlling element is combined with the measuring element, and consists primarily of an electrical contact closing device, which operates at predetermined high and low temperatures, thus closing or opening electrical circuits which energize or disconnect the operating element. The interior of the controlling element is shown in Fig. 1, from which it will be seen that the indicating arm is completely insulated from the operating circuits, the contacting device being frictionless. These controllers are furnished for all temperatures up to 3,000 deg. F., with high resistance movements for use either with base or rare metal couples.

The operating element consists of the device which actually regulates the heat supply in the furnace; as, for instance, in the case of a gas-fired furnace, a pair of electrically-operated gas and air valves, and in the case of an electric furnace, it consists of a special relay switch opening and closing the circuits of the heating element of the furnace.

FIG. 2—INTERIOR VIEW OF VAPOR TYPE THERMOMETER-THERMOSTAT.

An interior view of a vapor-type thermometer-thermostat is given in Fig. 2, complete with sensitive bulb, this type of instrument being adapted for use with a special relay switch, which is used when these instruments are employed for controlling temperatures in electric ovens and furnaces. The special design of contact closing device shown has proven very practicable and durable in long continued service. Both high and low contacts are shown in this illustration, but when used with the maker's automatic electrical controlling valves for both gas and air supply only one contact is required.

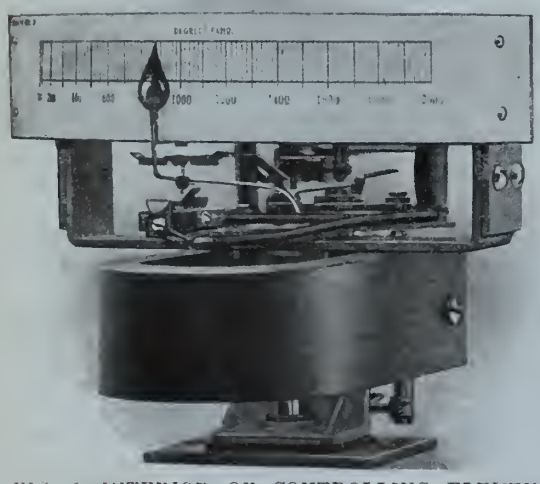

FIG. 1—INTERIOR OF CONTROLLING ELEMENT.

ANTI-ACID VALVES

THE Lunkenheimer Co., of Cincinnati, Ohio, state that during the past year there was an exceptionally good demand for valves made entirely of iron for use in handling cyanides and other solutions which attack metals having copper as their basic element, and which consequently could not be handled by brass valves or valves having any part made of brass. This company, we understand, have supplied a large number for use in dye and chemical manufacturing plants, but the demand was not confined to these sources, as quite a number were also supplied for use in mines, oil refineries, tanneries, pulp and chemical fibre mills, canning and packing establishments, etc. In the manufacture of these all-iron valves, a composition is used that is claimed to be exceptionally free from impurities, resulting in solidity of grain structure which insures great strength and makes the castings more resistent to corrosion and chemical attack. For handling the more severe solutions, such as caustic soda, caustic potash, soda-ash, and other similar alkaline liquids, the company employ a composition known as "Lunkenheimer Nickel-iron." The exceptional acid resisting qualities of this metal and the long and satisfactory service rendered has led many to use valves made of this material even for the weaker solutions. The standard line of Lunkenheimer All Iron Valves includes "Ferrenewo" Globe, Angle, Cross, and Check Valves in sizes as small as ¼-in., and up to 2 inches; cross valves, sizes 2 to 12 inches, inclusive; "Clip" gate valves, as small as ½ inch and up to 6 inches; "Victor" gate valves, sizes 2 to 12 inches, inclusive; quick opening gate valves with lever, sizes ½ to 12 inches, inclusive ,and check valves up to 12 inches inclusive.

Spon's Electrical Pocket Book. By Walter H. Molesworth. 488 pages 6¾ x 4¼ ins., 325 illustrations. Published by E. & F. N. Spon Ltd., London and Spon and Chamberlain, New York City. Price $1.75 net. This is a new reference book of general electrical information, formulae and tables for practical engineers. The book contains a great deal of useful information for electrical engineers arranged in compact form and written in a clear and concise manner. Some sections, namely, thosedevoted to essentially English practice such as British Board of Trade and Home Office Regulations, etc., will not be of much practical value in Canada, but as it is an English publication this feature could not be eliminated. It is however an excellent handbook and in all other respects will be a valuable reference book for engineers in almost any country. Being a pocket book, questions relating to design and detail have not been included, nor has space permitted of reference to telegraphy, telephoning and special branches of electricity.

TWIN FILTERS

With a Twin Filter there is no need of by-passing the water at any time, as there is always one filtering chamber in service.

The Twin Filter

Two separate filtering chambers each containing a filtering unit, which may be cleaned and replaced any time without interfering with the other. No interruption in service—no shut down or by-pass necessary while cleaning.

Safety demands all your feed water to be filtered to remove the oil, dirt, rust, etc., contained therein —it is a "safety first" policy. Impurities, especially oil, accumulate on the boiler tubes and increase the danger of boiler explosions.

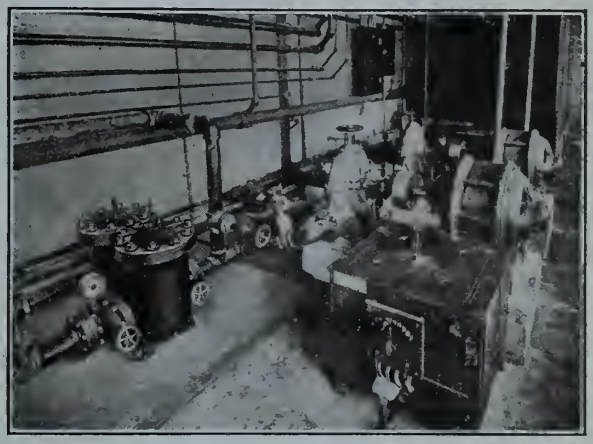
The same "safety first" policy should be followed with all your service water for it is easier to keep the sediment, etc., out of your apparatus than it is to remove it after it gets in—to say nothing of the wear and tear on the apparatus.

Mr. A. C. Ruhl, Chief Engineer for the American Gypsum Co., Port Clinton, Ohio, writes us in part under date of Aug. 16th, 1916, as follows:—"- - - I think if it were not for the Grease Extractor we would shoot our condensate into the river as there is too much oil going by the Oil Separator, especially on heavy load and high vacuum, but the Grease Extractor in the boiler feed line is there as a 'safety first', keeping our boilers free from oil.- - - "

Complete information about the Twin Filter and Grease Extractor in Bulletin "B." Send for a copy.

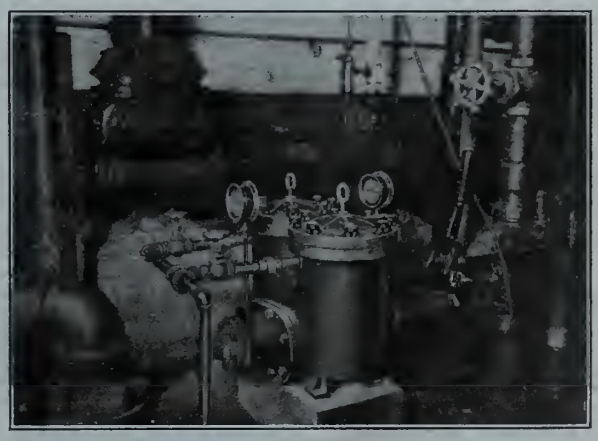
Elliott Company

6902 Susquehanna Street
Pittsburgh, Pa.



The Twin Filter shown above insures a continuous supply of clean water for the step bearings of the turbines in a large hydro-electric plant.

The Twin Filter shown above protects the coils of water-cooled transformers from being clogged up or coated with sand, sediment, etc.



The Twin Grease Extractor shown above insures an uninterrupted supply of boiler feed water, free from oil and grease, for a 5,600 h.p. battery of boilers.

Can you keep the pointer where it belongs?

It's getting near four o'clock. The demand for power is a trifle heavier than usual. The peak is coming. The sockets click one after another in a steady stream. The demand for steam is going up, up, up. Can You Keep The Pointer Where It Belongs?

Sturtevant
(TRADE-MARK)

Turbo-Undergrate Blower

will keep steam up. It supplies all the draft you want and just when you want it.

When you buy a blower be sure it's a Sturtevant. The Sturtevant name is a guarantee of mechanical excellence—a guarantee that you will have no breakdown and no bearing trouble.

The Sturtevant Set has generous bearings with oil rings and large reservoirs. One filling will last for weeks

To prevent the escape of steam from the casing there is a floating stuffing box. If for any reason through neglect or carelessness this is allowed to leak, there is a special "water-throw" collar which makes it impossible for steam to enter the bearings. Furthermore, the floating stuffing box makes it possible to exhaust against back pressures as high as 25 pounds.

If you have trouble getting enough steam or keeping the needle where it belongs, write us for bulletin No. 214-U.

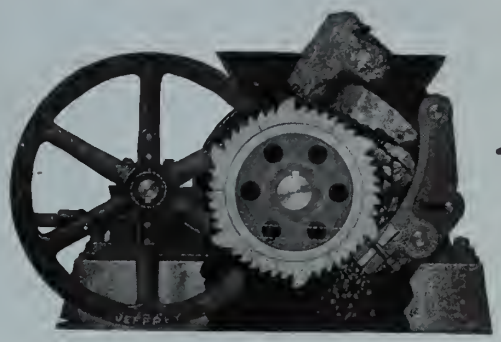
"THE RILEY STOKER"

One Operation Reduces large Lumps and Run-of-Mine Coal to the Proper Size for Greatest Stoker Efficiency



JEFFREY
SINGLE ROLL
CRUSHERS

are daily proving their worth for:

The Bethlehem Steel Co.
The American Steel & Wire Co.
The International Harvester Co.
The Anaconda Copper Mining Co.

and in scores of Power and Gas Plants, Railroads and Mining Industries.

In every detail of this rugged, high-class machine you are buying the results of years of experience in a wide field of actual service.

Special Features:

1. **It is Easily Adjusted for a Large Range of Sizes and Capacities.**
2. **Consumes but Little Power. Costs Little to Install.**
3. **It can be Started-up under Full Load. It does not require a Feeder.**
4. **Occupies Small Space in proportion to its capacity.**
5. **All Joints are Machined. Gears are of Steel with Cut Teeth.**
6. **It is Provided with an Efficient Safety Device which protects against ordinary shock and accident.**

Bulletin No. 141-4 Contains a Detailed Description of this Machine—with Testimonials and Illustrations of Many Installations. Send for YOUR Copy.

Projects and Developments

B. E. Michel has been appointed city engineer of Kitchener, Ont., at a salary of $1,800.

F. Tissington has resigned from the position of chief engineer of MacKinnon Holmes & Co., Sherbrooke, Que.

Stratford, Ont.—The Public Utilities Commission has decided to purchase a number of fire hydrants for better fire protection.

Trail, B.C.—A by-law will be submitted to the ratepayers on May 22 to raise $80,000 for extensions to the waterworks plant.

The Chapman Valve Mfg. Co., Toronto, have been awarded a contract for 24-inch valves for Price Bros., paper mill at Shipsaw Falls, Que.

Swift Current, Sask.—The Local Government Board has given permission for the issue of $55,000 debentures for the purchase of a Diesel oil engine.

Three Rivers, Que.—The City Council are receiving bids on four turbine pumps, each having a capacity of between 2½ and 3 million gallons per day.

T. M. Jones, of Canadian Allis-Chalmers, Ltd., has joined the staff of the Bawden Machine Co., Toronto, as chief engineer and general manager.

Davidson, Sask.—A by-law will be submitted to the ratepayers on May 21 to raise $8,000 for the construction of a new school and $4,500 for power house improvements.

Aylmer, Ont., proposes to spend $7,000 for the installation of electrically driven pumps for its waterworks system and a gasoline pump for fire purposes.

Three Rivers, Que.—The St. Maurice Lumber Co., propose to erect a power house for six units of 10,500 h.p. and a concrete dam 1,080 feet long. R. F. Grant is manager.

The Bawden Pump Co., Toronto, have been awarded a contract for nine pumps, ranging from half-million to three-million gallons' capacity per day, by the Colonial Pulp & Paper Co., Vancouver, B.C.

Hamilton, Ont.—The Board of Control has decided to install a refrigerating plant, the cost not to exceed $6240, in the new mountain hospital. This was the amount of a tender made by the Canadian Ice Machine Co. of Toronto.

C. N. Schrag, sales engineer of the Ontario District Office of Canadian Allis-Chalmers, Ltd., has resigned to become general sales manager of the Bawden Machine Co., Sterling Road, Toronto.

T. S. Downham is again actively connected as manager with the Canadian Steam Boiler & Equipment Co., Toronto, after a holiday of several months duration. Mr. Downham has fully recovered his health.

Hamilton, Ont.—City Engineer Gray reports that additional transformers are required for the Beach pumping station. The cost is estimated at $20,000. The Board of Control has the matter under consideration.

Guelph, Ont.—The Water Commissioners have awarded the following contracts for annual supplies:—Cast iron pipe, National Iron Works, Toronto; valves, Kerr Engine Co., Walkerville; brass goods, Canada Brass Co., Galt.

St. Lambert, Que.—Tenders will be received up to May 28, for the supply and installation of a horizontal shaft centrifugal pump, electric motor and switchboard. Specifications may be obtained from H. A. Gibeau, town engineer.

Rosthern, Sask.—A by-law will be prepared to raise $25,000 for the purpose of purchasing an electric light plant. Underwood & Murphy, engineers, of Saskatoon, have advised that a 100 h.p. plant be installed but the council favors a 75 h.p. unit.

Alliston, Ont.—It is proposed to raise $32,000 to provide for the taking over of the Alliston electric light plant and repairing and improving same for the purpose of distributing electric power to be supplied by the Hydro-Electric Power Commission of Ontario.

St. John, N.B.—Tenders will be called shortly for the erection of a power house and laundry at the General Hospital. The estimated cost is $46,000. Full particulars may be obtained from F. Neil Brodie, architect, St. John, N.B.

I. J. Tait, formerly chief engineer at the Windsor station, Montreal, has recently become associated with J. T. Farmer, sales representative for the Green Fuel Economizer Co. and the Combustion Engineering Corporation of New York.

J. T. Farmer, 314 Coristine Bldg., Montreal, who for several years has handled the Canadian business of the Green Fuel Economizer Co. of New York, has in addition to this, the agency for Canada, for the Combustion Engineering Corporation also of New York; this firm manufactures a line of underfeed stokers.

Toronto, Ont.—Tenders will be received up to Tuesday, June 5th, 1917, for the sale and removal of four horizontal return tubular boilers from the west boiler room of the City Hall, Toronto. Copy of terms and conditions may be seen, and tender form obtained, together with all information relative thereto, at the offices of the Property Department, City Hall.

Aurora, Ont.—At a meeting of citizens held in the Town Hall here on May 2, E. C. James, civil engineer for the county, explained a suggested sewage system for the town, illustrating the plan with diagrams. The estimated cost of the improvement is $80,000, and it was the opinion of the meeting that the matter should not be considered until after the war.

Winnipeg, Man.—Tenders for the supply of valves for the Greater Winnipeg Water District were as follows:—Crane Co., Chicago, $15,038.70; Canadian Fairbanks-Morse Co., $12,749.92; Kennedy Valve Co., Elmira, $12,345.44; Rensselaer Valve Co., Troy, $12,196.54; General Supply Co., Winnipeg, $12.184; Drummond, McCall Co., Montreal, $11,138.25. No tender was accepted.

Brantford, Ont.—Tenders will be received by the secretary of the Board of Water Commissioners, until May 28, for two electrically-driven turbine pumps with capacity of 300 gallons per minute each, also electric motors and equipment. Specifications, etc., may be seen at the office of the secretary of the Board, Brantford, or at the engineer's office, Chipman & Power, Mail Building, Toronto.

Winnipeg, Man.—Tenders, addressed to the chairman, Board of Control, will be received up to May 18 for the supply and delivery, f.o.b. cars Winnipeg, freight and duty paid, to siding on Saskatchewan Avenue at the Decarie incinerator, of two horizontal water tube boilers. Plans, specifications and form of tender may be obtained at the office of the city engineer, 223 James Avenue.

Elmira, Ont.—The ratepayers will vote on two by-laws on May 28. The first calls for a loan of $15,000 to the Elmira Transmission and Machinery Co. The

UNIFORM TEMPERATURES

Help produce better results at lower costs.

SARCO

TEMPERATURE REGULATOR

automatically maintains a uniform temperature at all times.

Watch It Work

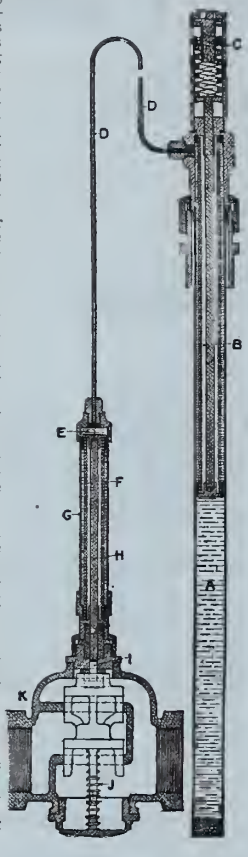
Thermostatic Tube A-B-C automatically operates the Controlling tube F-G-H.

In the Tube A-B-C, A is heavy hydro-carbon oil—which expands and contracts as the surrounding outside temperature varies. B is the spirally corrugated tube capable of expansion and contraction by the adjustment screw C, thus permitting a most minute and accurate adjustment for the maintenance of uniform temperature.

D is a small bore, heavy walled piece of tubing connecting both the sections, and making a closed system hermetically sealed.

In the controlling tube, F-G-H, is found the hydraulic principle so successfully employed in the Steam Trap Sarco. F is the corrugated expansion tube, G and E the sensitive heavy hydro-carbon oil, and H the piston plunger operating the balance valve K.

As the temperature increases at the location of thermostatic Tube A-B-C, the fluid A expands through the pipe D and develops hydraulic pressure against the head of tube F at the point E, thus depressing the piston H and closing the valve.



An operation entirely automatic and by hydraulic pressure. This operation is reversed as outside temperature decreases.

Sarco Temperature Regulator has many unique advantages. It is wholly self-contained and creates within itself sufficient hydraulic power to operate positively against any given pressure up to 200 pounds. It is small, compact, durable and 100% automatic.

Sarco Temperature Regulators are specially made and tested to meet the particular conditions for each installation, and they operate with equal efficiency for either gas, steam, water (hot or cold), or any liquid. They have a range for any given temperature from 60 to 250 degrees Fahr., and have an individual adjustment variation of 20 degrees. Regulators for higher or lower temperatures may be specially manufactured.

Sarco Temperature Regulators contain neither rubber, leather, nor metallic disc diaphragms. Low first cost, no maintenance, and require practically no space.

Write for Bulletin J—2.

SARCO COMPANY INC.

Woolworth Building New York,

Drexel Bldg., Philadelphia
New Telegraph Bldg., Detroit and Monadnock Block, Chicago
Canada: Peacock Brothers, Montreal

second provides for granting to the Phonola Co., of Canada, a free deed of $2,500 mortgage. The first company would increase its capacity by the addition of buildings 50 x 50 feet and 50 x 88 feet, and an extra dry kiln. The second company will begin operations at once.

Brockville, Ont.—The engineers are at work installing the cold storage apparatus in the new buildings of the Laing Produce and Storage Co., which was formerly occupied by the Bowie Brewing Co. The company expects to start work immediately on the installation of a milk condensing plant, which will have a capacity of 75 tons of milk daily. It is expected that this portion of the plant will be in operation by September 1st.

S. R. Sheldon, vice-president and chief engineer of Sheldon's Ltd., Galt, Ont., the well known manufacturers of heating and ventilating equipment, died suddenly after an operation for appendicitis aged forty. Mr. Sheldon was originally with the McEachren Ventilating Co. and about fifteen years ago took over the business with his brother W. O. Sheldon. The company was at a later date incorporated as Sheldons Ltd.

Regina, Sask.—Work on the construction of the new power house at Boggy Creek will be commenced shortly and the order for the new three million gallon electrical pumping unit will be placed before the end of this month. When the new unit is installed the capacity of the plant will be nearly doubled, and it would be possible to pump seven million gallons a day if that amount were required. The estimated cost of building and unit is in the neighborhood of $10,000. Two transformers will also be installed.

Mason Regulator & Engineering Co.—A new company has been organized in Montreal, under the name of Mason Regulator & Engineering Co., and has taken over the well known steam specialty business of H. L. Peiler & Co. there. The new company has also acquired the Canadian business of the Griscom-Russell Co. Eldon Macleod, treasurer of the Mason Regulator Co. of Boston, Mass., is president, while H. L. Peiler will act as treasurer and general manager. It is the intention of the new company to manufacture, in Canada, Mason reducing valves and other pressure regulating appliances, as well as "Bundy" steam traps and "Coppus" blowers besides the marine and steam specialties of the Griscom-Russell Co. These include the well known Reilly heaters, evaporators and distillers which enter so largely into marine equipment. All the other agencies controlled by H. L. Peiler & Co., will be retained, the business being carried along on the same lines as heretofore. The new company will have a greatly strengthened organization. Associated with Mr. Peiler will be E. J. Hatton, formerly of the Canadian Allis Chalmers Co., who will have charge of the manufacturing and erection work, while the sales end will be taken under Mr. Peiler's supervision, by E. T. Jeffrey, formerly of the John McDougall Caledonian Iron Works, and H. E. Kirkham. The Toronto office will be in charge of J. Collins, late manager of the Canadian Steam Boiler Equipment Co., who is well known to the engineering fraternity in Toronto. The offices of the old firm at 380 St. James St., Montreal, have been overhauled and additional space acquired for taking care of the increased business anticipated.

CATALOGUES

Niagara Motors.—Bulletin being distributed by the Niagara Motors Corporation, Buffalo, N.Y., dealing with an interesting line of gasoline motors for power boats. Specifications give the principal dimensions and weights, etc., of the various models, some of which are illustrated and their principal features described. A number of power boats are also illustrated featuring the suitability of "Niagara" motors for various kinds of service.

Searchlight Projectors.—An interesting catalogue has recently been issued by Crompton & Co., Chelmsford, England dealing with searchlight projectors for naval and military and general purposes. The catalogue contains a general description covering a wide range of sizes of standard searchlight projectors including particulars of the main features of their construction. The various types are illustrated and particulars given regarding current and range etc. of all sizes. The concluding pages contain information covering special attachments and applications.

Cameron Babbitt Retainer

(Patented in Canada and the U.S.A.)

Not like clay or other material, as it does not stick to the work or hands. Does away with using leather or paste-board at end of box.

The only satisfactory compound for retaining molten metal and can be used over and over again for months—no deterioration.

For any metal.

A.S.K. Chemical Company, Elora, Ontario

Step up, boys, and meet Jeff Erson

Jeff is a sort of a specialist. He's made a thorough study of a subject in which every power plant engineer and naturally every superintendent is vitally interested—the elimination of leaks in power lines.

He has found that whether it be a high pressure steam line, an air line or a water line, its connections will give less trouble if they are made with

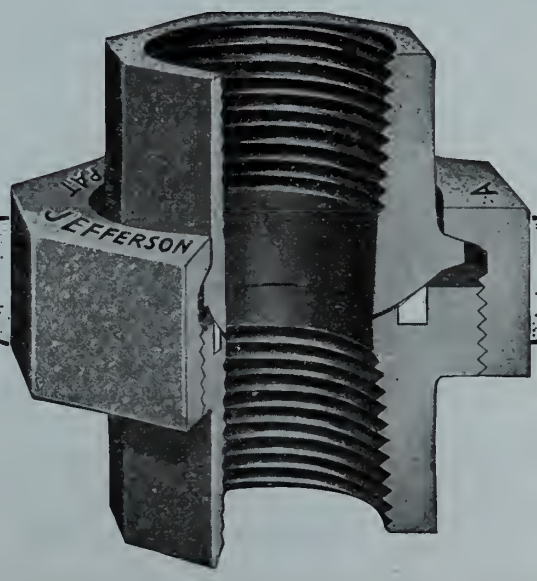
Jefferson Unions

He is going to be with you in Canadian Power House every month and he is going to show you just where it is to your advantage to hook up every line in your plant both on high and low pressures with Jefferson Unions.

So watch out for Jeff—we assure you his little monthly visit will be profitable to you. And, we almost forgot, Jeff has a well-worth-having book he wants to give you. Just drop a card to him at the address below.

Jefferson Union Company

Lexington, Mass.



If any advertisement interests you, tear it out now and place with letters to be answered.

It may never happen to you—but are you SURE it WON'T?

Accidents due to high and low water are occurring continually. Your plant may never suffer, but have you assurance that it won't? Have you taken the necessary precautions against this danger?

The Vigilant Feed Water Regulator is guaranteed to keep water level within ¼" of middle gauge. It is a positive prevention of dangers arising from high or low water.

Investigate it to-day!

Wanted—

Engineers to contribute to the Power House

THIS is a practical paper for practical engineers. It is an educational medium and out to help its readers. It is a technical school and a social meeting place combined. It is first, last and all the time an engineer's paper.

If you should meet two or three or a dozen of your brother engineers you would swap ideas—you'd tell of some idea you had worked out in your plant. Others would describe some pet schemes they had devised. And so you would be mutually benefited.

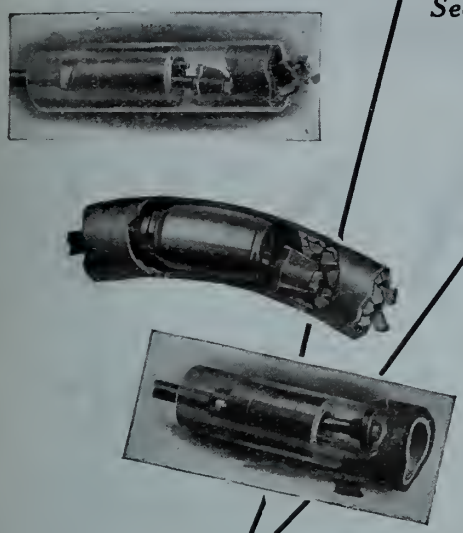
Why not make the Power House your monthly meeting place? Why not describe in this paper some kink or scheme you have worked out and found successful? We will pay you for it and you, in turn, will be multiplying the usefulness of your idea five thousand fold!

Never mind polishing up your letters—just give us the idea; that's the main thing. Never mind how crude your pencil sketch may be. We have draughtsmen who will finish up your drawings so they may be reproduced.

Try this idea a time or two and see how much satisfaction you'll get out of it. Start the ball a-rolling and thus help other engineers, yourself and your paper.

THE POWER HOUSE, 143-153 University Avenue, Toronto

A Louisiana Lumber Company Generated 33 1/3% More Steam Using This Tool



See Square below

The Pelican Cooperage & Lumber Co., Mound, La., required 33 1-3% more steam. At first, they thought about installing a new 150 H.P. boiler. Then they saw one of our advertisements, sent for a tool, cleaned up their boiler tubes and produced 33 1-3% more steam—with the

Dean Boiler Tube Cleaner

You may try this cleaner in one of your own boilers FREE. Simply write "Send me a Dean for free trial," giving type of your boilers and outside diameter of the tubes. There are no strings to this offer. You are the judge. If the tool is not satisfactory, you ship it back at our expense; if it is O.K. we issue with every Dean Cleaner sold a guarantee that it will pay for itself in six months' time, or your money back.

Write, anyway, for booklet 136, "The Logic of the Dean."

BETTER THAN BRONZE

THE NATIONAL MANUFACTURING CO., LTD.

Brockville, Ont., Sept. 27, 1916.

Magnolia Metal Co.,
Montreal, Que.

Dear Sirs:

We have been using Magnolia Metal for some time with good results. We are making Shrapnel Shells and have been finishing the body on the Ford-Smith grinder. These grinders come equipped with bronze bearings which give us a lot of trouble. We looked about for a substitute and tried Magnolia with very satisfactory results.

Yours truly,

THE NATIONAL MANUFACTURING CO.

PRACTICAL ENGINEER POCKET BOOK:

Over 600 pages. A valuable reference work imported from England and sold as an advertising medium at the low price of 40c post paid.

Address Montreal Office.

SOLD BY LEADING DEALERS EVERYWHERE OR BY

MAGNOLIA METAL CO.

Oil in the Arctic

CANADA possesses enough petroleum to last the world for a thousand years. This oil is found on the Mackenzie River — in the Arctic region. The discovery was made two years ago by Dr. T. O. Bosworth, who reported the story of his "find" to the Dominion Government, but it is only now that the people of Canada have given them the story of a national asset of momentous importance. The tar sands north of Athabasca and Great Slave Lake become oil fields of incalculable value near the mouth of the Mackenzie. Read this story, told by Dr. Bosworth himself, of Canada's and the Empire's exhaustless oil fields in

MACLEAN'S MAGAZINE *for* June

THEN have regard for the following highly interesting special articles and features of the June MACLEAN'S, always keeping in mind that they are by Canadians for Canadians—and so belong by right to MACLEAN'S MAGAZINE, whose elect purpose is to advance the development of Canadian writers and Canadian literature, and to make the Canadian people —the best of them—better informed concerning their own land and their distinguished sons and daughters.

Balfour at Washington

and the war preparations of the United States, by Agnes C. Laut. An interpretation of Balfour's mission to America as it relates to the Allies' cause and to the unifying of the great Anglo-Saxon peoples into an organized power for the conservation and development of human liberty and the rights of the common people.

William T. Dewart

A Character Sketch

The romantic and inspiring story of a Canadian—a member of a well-known Ontario family—who is now general manager of the Munsey publications in New York. The story is exceedingly well told by a remarkable man—Erman J. Ridgeway, himself a publisher of brilliant record.

Putting Pep into Parliament

The idea is that the work and proceedings of Parliament should be simplified and speeded up. Parliament is becoming more and more of a business institution and less and less a place for oratory. The work of Canada is too important and too vast to permit of elocution and casuistry and wire-pulling. **H. F. Gadsby**, a writer with any amount of "pep" himself, is the man who pleads that Pep should be put into Parliament.

Sunshine in Mariposa

By Stephen Leacock

The second instalment of his play whose setting and incidents are found in Ontario, Leacock's birthplace. Rich humor, and revealing Canada's premier humorous writer in a new phase of his astounding versatility.

James B. Hendryx

continues "The Gun Brand." This is a romance of the Canadian Northland. An adventurous and ambitious girl teaches school in Athabasca, and in her journeyings thither and in her life and work later on, there are incidents and experiences and developments laden with thrills. A fine story which can be satisfactorily begun in the June MACLEAN'S.

Sir Gilbert Parker

contributes "At Lake O'Calling."
This is a Canadian story—about the building of a railroad for Empire business. A romantic tangle gives the story zest and shows Sir Gilbert's art finely. Probably his best story ever appearing in MACLEAN'S MAGAZINE

A. C. Allenson

contributes "June Comes Back."
A very beautiful June bride story—about June Summers, a charming young woman.

Arthur Beverly Baxter

contributes "The Man Who Scoffed." A war story—and good war stories at this time have great appeal. We all want to know more about the life our glorious Canadian boys are living in these epochal days. Romance mingles itself with death and tragedy.

Hopkins Moorhouse

contributes "The Herald Angel."
One of his fine Andy Doolin stories—a story of the days of the forty-niners with their lawlessness and enriching labors. A story of valor and primitive passions in freeset exercise.

Records of Success

This is a feature department of MACLEAN'S given over to sketches of interesting Canadian men and women who have accomplished things.

Review of Reviews

A department tremendously well liked by every MACLEAN'S MAGAZINE reader, for here are found condensations of many articles of surpassing interest appearing in other magazines. So do readers keep themselves informed concerning what is best and most vital in current thought and life.

SO you have evidence of just how much worth-while MACLEAN'S MAGAZINE is—how admirably it is doing its chosen work and realizing its own purposes; which are to give the Canadian people a magazine dominantly and usefully Canadian, and which will satisfy from beginning to end.

At all News-dealers, 15 cents

"I have about 25 Davis Traps of various sizes in service, the majority of them for 22 years. I will gladly recommend them at all times," wrote H. F. Hustedt, Chief Engineer, Tulane University, New Orleans, when ordering his first repairs.

Possibly all Davis Traps would not last that long without repairs. Much depends on the operating conditions. On some installations they last longer than on others. But all Davis Traps have Tobin Bronze seats and valves—a hard, tough metal from which long service may be expected.

And when these vital parts of the trap do wear out, they may be easily renewed at slight expense.

We make Pressure Regulators . Balanced Valve . Float Valve . Steam Trap . Back Pressure Valve . Exhaust Relief Valves . Stop and Check Valves . Pump Governors . Damper Regulators . Radiator Air Valves . Emergency Stop Valves.

Mechanical Regulation of Boiler Feed Water

By the use of the "S-C" method you are assured of a continuous feed at all times load is on boiler. The graduation in rate of feeding is entirely dependent upon the load and fire conditions. The Regulator will carry a constant level on steady load—higher level on light load and lower level on peak loads. Variation in water level is entirely dependent on inclined position of generator which is adjustable while operating under full load.

Bulletin No. 80 explains all.

Generator or Actuating end of Regulator.

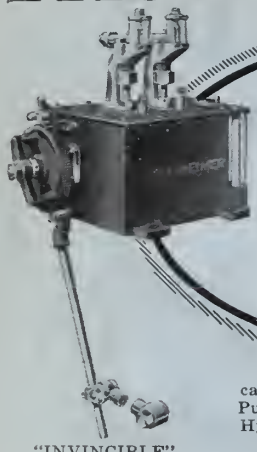
"Friction losses minimized"—



"INVINCIBLE" Mechanical Oil Pump

spells efficiency in power production and increased life to the bearing of power units. Of equal importance to using the most suitable lubricant is the device for feeding it, and the type used should be governed by the service conditions to be met. The lubricator should utilize every drop of oil put into it, the feed should be easily regulated, positive and uniform. From the extensive line of

LUNKENHEIMER Cylinder Lubricators

"JUNIOR" Single Connection Hydrostatic Lubricator

can be found a type for every service condition, from the Multiple Feed "Invincible" Mechanical Oil Pump for High Pressure Steam and Diesel Oil Engine Cylinders to the small size single connection Hydrostatic Lubricator for Steam Pumps and Portables.

Every one a practical design—developed for a particular service; highly efficient in operation and very durable. Let us help you choose the type best suited to your individual case.

The Hand Oil Pumps are for use as auxiliaries to the cylinder lubricator, for forcing an additional quantity of oil to the cylinder when starting or for emergency.

The name "Lunkenheimer" on the lubricators of steam power units is a guarantee of service, satisfaction and economy.

Specify "Lunkenheimer" and insist on having the genuine.

Your local dealer can furnish them; if not, write us.

Write for Booklets 526—DC and 572—DC which illustrate the most complete line of high grade lubricators made.

Plibrico—Endorsed by some of the leading Engineers as the GREATEST FURNACE LINING OF RECENT TIMES

Plibrico—makes a solid one-piece lining without joints. Absolutely gas and air-tight. Saves its cost in fuel in a month or two—you will have a steady fire with less effort and less coal by using it.

Plibrico—is mixed ready for use, requires only half the time to install and does not require skilled labor. Any laborer who is at all familiar with the building line can use it. DOES NOT BREAK, CRACK OR SHELL OFF LIKE ORDINARY BRICK.

Can be used for front door arches, side walls, brick walls, combustion chamber and rear arches. *Sets quickly*—after a few hours with a low fire to drain out the moisture, you may fire up as usual. No special forms required.

Ideal for temporary repairs. Better order a bærrel and have it ready for an emergency.

Plibrico Bond—A high temperature cement for repairs

"PLIBRICO BOND" is a product which gives a perfect bond between fire-brick, and does not allow the fire to burn out the joints, as is the case where fire-clay is used. Prevents furnace walls from cracking and crumbling.

It's the most practical and logical high temperature mortar you can use. It's the ever-ready repair cement that you should have in case of emergency.

GARLOCK

PUMP VALVES

The service of pump valves depends upon the compounds as well as the consistency and cure of the valves. The compounds used in Garlock pump valves have been established after years of trial in actual service and under the most severe conditions. Pump valves should always be used for the purposes for which they are intended. The following are a few of our leading styles and grades of valves:

Style No. 139—For medium pressure cold water
" " 175—For high pressure cold water
" " 182—For warm or greasy water
" " 108—For hot water
" " 105—For boiling water
" " 154—For air compressors and condensers

We guarantee our pump valves to give satisfactory service when used under conditions for which they are intended.

Sales Offices in all Centres *Representatives Everywhere*

WE watched them run the big truck out of the yard: smoothly, almost noiselessly, it glided away. And in our minds we contrasted this with the noisy vehicle of ten years ago.

But almost any product can show improvement. Our own particular line has seen this change. The workman who objects to CLING-SURFACE "because it is hard to use" reminds one of the old lady who doesn't like automobiles because "they make so much noise." For the new semi-liquid CLING-SURFACE is perhaps easier to use than any belt dressing you can buy.

* * *

Changing it from the heavy paste of twenty years ago to the semi-liquid of to-day was not a simple problem. Not until 1915 were we ready to place it on sale. The preservative nature of CLING-SURFACE would not permit the use of any solvent, such as gasoline or turpentine. Nothing evaporative could be employed, as CLING-SURFACE must not oxidize, turn rancid or form sediment, for what it does in the open it will do in the belt, and there it should preserve and lubricate the fibres.

So, while twenty years ago it was necessary to heat the CLING-SURFACE, to-day (in ordinary temperatures) it is used cold.

CLING-SURFACE is applied with a stick, say two feet long by one or two inches wide and half an inch thick, around one end of which is wound and wired a cloth bandage. At no time, therefore, is the operator in danger, for he is able to keep away from all moving parts.

* * *

CLING-SURFACE immediately stops the belt slip and removes any static electricity in the drives. Its continued use means mellow, pliable, waterproof and slip-proof belts, long-lasting and hard-working, saving you in power, oil, belting, coal, trouble, and men's and machines' time an amount annually which makes the price of CLING-SURFACE insignificant.

Ask us for the plan 10,000 firms have found successful. Our co-operation is free and our guarantee means something.

Remember, use CLING-SURFACE and you wont need belt dressings.

What Gives Value to Trade Names

IN these days when a trade name may be made to be worth a million dollars or so a letter, the desire of manufacturers to find the proper trade name can well be understood.

To all manufacturers there is a valuable suggestion in what the American Ever Ready Works says about its new trade name, "Daylo," as reported in *Printers' Ink* last week. This name was selected on the basis of a referendum to the public. It was chosen by competent judges as the best of the thousands of names submitted, and yet the company confesses itself somewhat disappointed in the results.

"We had hoped," it said, "perhaps to obtain a word that would satisfactorily combine in a suggestive way both what Eveready is (powerful, portable electric light) and the variety of service it renders. We are now convinced that no usable protectable word could cover so broad a field."

But every manufacturer who has developed a successful trade name knows that if the company advertises persistently some day the word "Daylo" can be made to mean just what the company wishes it to mean. "Kodak" in the beginning had no meaning whatever. It was an arbitrary collection of five letters. But to-day consumers know what Kodak means because the company has given it a precise meaning through its years of intelligent advertising.

The American Ever Ready Works need not feel disappointed; but *its work is just begun. It must now give a meaning to "Daylo" which everybody will understand, and that means advertising. "Daylo" can be made to mean as much or as little as the company will. If the company depends upon the word alone to do the educational pioneering for the company's goods, it will mean little. If a strong volume of educational advertising is put behind the name, in time it can well prove its value to be worth a million or even two million dollars a letter.*

This is good philosophy, gentlemen, be it applied to flashlights or to files; to furnaces or forging presses or any other product.

Good advertising will give a name a value and a significance which it could not otherwise possess. Yes, advertising goes even further than that, because it creates in the buyer a sense of security and a feeling that there is something in the advertised product besides mere material, brains and skilled labor.

THE CANADIAN FAIRBANKS-MORSE COMPANY, LIMITED

CANADA'S DEPARTMENTAL HOUSE FOR MECHANICAL GOODS

STANDARD SUPER-HOT SPECIAL SOFT RED CONDENSER

Rub-Steel Valves

"THE VALVE WITH A BACKBONE"

WHAT IS IT? The Rub-Steel Valve is a valve made by a combination of rubber and steel.

THE CONSTRUCTION The construction consists of a plate of high grade steel placed in the center of the valve with a specially tough and lasting rubber composition on each side and edge, attached securely and lastingly to the metal by the Elchemco process, which chemically unites the rubber and steel.

THE PURPOSE The steel plate gives such strength to the valve that the highest pressure cannot warp, twist or in any way get it out of shape, while the rubber surfaces afford the proper seating qualities. **"Better than Metal Because of the Rubber—Better than Rubber Because of the Metal."**

WHAT IT ACCOMPLISHES It gives the valve a rigidity of form. It keeps the surface of the valve in its normal true position and insures a better seating quality. It prevents the high pressure from forcing the valve through the grating. It prevents the rubber from breaking up and the pieces causing trouble. It holds the surface of the valve in shape, so that when one side becomes worn the valve can be reversed without dressing. It is thinner and therefore gives greater efficiency to the pump. It permits the use of a softer valve for hot water, thus securing a better seat on worn or uneven "grids." It ensures an even distribution of the pressure, preventing "dishing" and the consequent cutting of the valve.

WHY YOU WANT IT **Because** its ultimate cost is less than that of ordinary type valves. **Because** it will last longer than other valves. **Because** it saves time and annoyance of replacement. **Because** its construction at once appeals to you as practical and sensible.

MARTELL
PACKINGS
MEAN
MORE
POWER

Ask "the man who knows" in any power plant what he thinks of the Martell Packings. We will leave it to his verdict. Power House experts know the worth of these packings by their good name or by actual experience with them.

Failure is out of the question with these packings.

Cut at a tangent to piston rod, and joints on diametrically opposite sides of piston are parallel. This arrangement of the joints of the ring allows the parts to adjust themselves to slight inequality of wear in the diameter of the rod, as they float freely. Therein lies superiority of Martell packings. WHY NOT GIVE THEM A TRIAL?

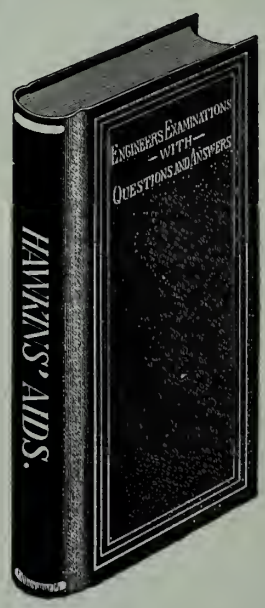
Hawkins' Aids
Free to Engineers



This work is an important aid to engineers of all grades, and is undoubtedly the most helpful ever issued relating to a safe and sure preparation for examination. It presents in a condensed form the most approved practice in the care and management of Steam Boilers, Engines, Pumps, Electrical and Refrigerating Machines, also a few plain rules of arithmetic with examples of how to work the problems relating to the safety valve, strength of boilers and horse power of the Steam Engine and Steam Boiler.

It contains various rules, regulations and laws of large cities for the examination of boilers and the licensing of engineers.

The book gives the underlying principles of steam engineering in plain language, with very many sample questions and answers likely to be asked by the examiner.

It also gives a short chapter on the "Key to Success" in obtaining knowledge necessary for advancement in engineering.

This helpful volume contains 200 pages of valuable information not elsewhere obtainable; it is bound in rich red leather with full gold edges and titles; it measures 5x7½ inches, and weighs twenty-two ounces.

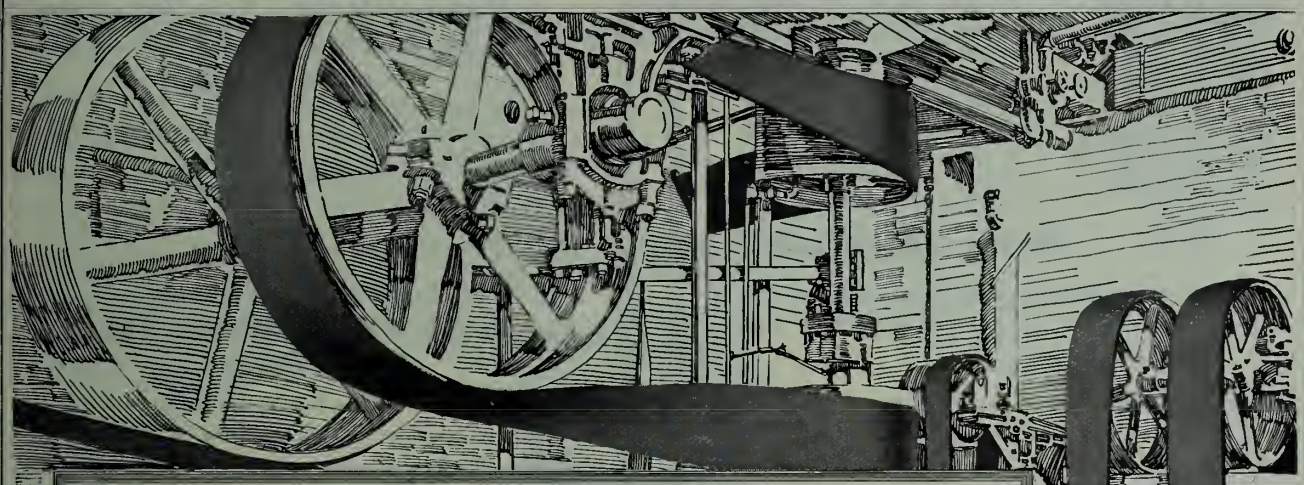
GRATON & KNIGHT
Standardized Series
LEATHER BELTING

Tanned by us for belting use



"Let's scrap our belting specification," said the Master Mechanic

The Purchasing Agent was startled. "Why?" he asked.

"It doesn't protect us," replied the M.M. "We buy lots of belting for First Quality that proves to be mixed with seconds and shoulder. We can't test every roll—and you know mighty well there's nobody in this shop wise enough to detect skillfully mixed belting."

"What'll we do?" inquired the P. A.

"I'd advise that we adopt the Graton & Knight Standardized Series as our own belting standards. They're the largest belt makers in the world—been 66 years developing and classifying their Series of Brands, until it covers every possible belt need. And the individual Brands run absolutely uniform—I've used enough to know that."

"How does it work?"—the Purchasing Agent was interested.

"You simply get a set of the Graton & Knight Standardized Belts as recommended for our needs, with the official description of each. Then when you need a belt, you select the brand that's right for the job—get bids on that or equal. Thus you make *actual service* the basis for comparison—not just a written specification."

"I'll go you, Joe," cried the P. A. "If there's one thing I've always wanted to standardize, it is our belting—but I haven't known how to go about it. I'll have the Graton & Knight salesman come and tell us how to do it. Be sure you're there, Joe."

* * *

Are YOU buying belts on discount—or on performance?

Do you KNOW when your specification is met—or do you take a chance?

The only way to be sure of belting is to have a simple, safe and trustworthy set of real belting standards to go by. Graton & Knight Standardized Series furnishes this.

Write to-day for the Graton & Knight Belting Book—or have the nearest Graton & Knight representative call on you.

RELIABILITY

What is more essential than reliable power transmission? A hot box can tie up production for hours, till repairs are made.

Are you still using plain bearings on your lineshafting? If so, then you know the countless troubles that are ahead of you. Hot boxes, worn bearings, rebabbitting, continuous oiling—all of these are trouble-makers and mean delay.

This delay can be eliminated. You can put an end to all trouble by using S K F Self-Aligning Ball Bearing Hangers. S K F Ball Bearings do not wear down; they do not heat. They are positive preventers of trouble.

Send for information.

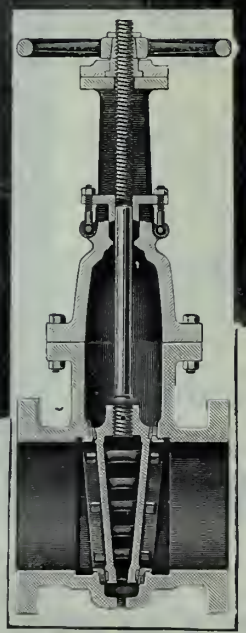
Pratt & Cady
Renewable Seat Ring
Valves



PIPING installation at low level pumping station, Montreal. Marked valves indicate 12-inch Pratt & Cady semi-steel valves on the superheated line to the main pumping units. Pressure 150 lbs. per inch.

Pratt & Cady valves are made for every service in many patterns and weights. They are easily operated, take pressure from either side, and will not wedge. Seat rings are easily renewable without removing the valves from the pipe line. The "choice of engineers who know" for over fifty years. They always satisfy. Ask for our catalog.

Manufactured by **Pratt & Cady, Inc., Hartford, Conn.**

ALBANY GREASE

is a most efficient, economical and dependable lubricant. It can be used, on account of its high lubricating qualities and its low melting point in any kind of grease cup and for every bearing in your plant. Use Albany Grease on your engines, pumps, compressors, motors, line shafting and special machines—always. We will gladly send you a quantity of Albany Grease to try and an Albany Cup. No charge of course. Write—now.

ALBANY LUBRICATING CO.
708-10 Washington Street, New York
ESTABLISHED 1868

Detroit Lubricators

Have Given Satisfaction For Forty Years.

Built in a sufficient variety of styles to lubricate properly every type of steam engine, pump, gas engine, air compressor, etc.

Send to-day for catalog L 1. The information on lubricating devices contained in it will be valuable to you.

THEIR efficiency holds over half the world's trade.

Holtwood Plant, Pennsylvania Water & Power Co., Waterproofed with R.I.W. Toxement.

Is Your Fireproof Building Waterproof?

In specifying modern Portland Cement construction for your new building, you have minimized the chance of loss by fire. But are you protected against loss by depreciation from water?

At a small additional first cost you can make your fireproof building permanently *waterproof* with

R.I.W. TOXEMENT
REMEMBER IT'S WATERPROOF
REG. U.S. PAT. OFF. PATENTED

This integral waterproofing compound is a dry powder, mixed in small quantities with Portland Cement or clinker. It lubricates the batch of cement, concrete or stucco, and causes the ingredients to knit together in a dense, impenetrable mass.

It does not accelerate or retard the setting, and its use results in a construction that is permanently proof against salt or fresh water. Write for descriptive literature, Dept. 59.

For Small Powers or Large Powers

Morse Silent Chains

Deliver the Goods

YOU will admit that loss of power means loss of production. You know that belts slip and lose power. Any mechanic will tell you that gearing becomes less efficient as the tooth wear increases.

Therefore speeding up present productive equipment is simply a question of using that transmission system which CANNOT slip and lose power, and DOES NOT decrease in efficiency as it ages.

Silent chains as a class combine all of the advantages of belting and gearing without their disadvantages. MORSE Chains are best, yes BEST, in the silent class because their exclusive "Rocker-Joint" operates on a "rolling" friction principle, while all other chain joints operate on a "sliding" friction principle.

Take any two objects handy. Roll one and slide the other over your desk and you will *see* why MORSE Chains last longest and are most economical.

The coupon opposite is a convenient invention for your consideration of this subject.

NOTICE

TO

Stationary and Hoisting Engineers

Everyone operating a STATIONARY steam plant of 50 h.p. or over in the Province of Ontario must hold a Stationary Engineer's Certificate from the Board of Stationary and Hoisting Engineers. Anyone operating such a plant without a Certificate is liable to the penalties set forth in the Stationary and Hoisting Engineers' Act.

Everyone operating a HOISTING steam plant working at a pressure of 20 pounds or over, irrespective of horse power, and used for hoisting in structural operations or excavating purposes, in the Province of Ontario, must hold a Hoisting Engineer's Certificate from the Board of Stationary and Hoisting Engineers. Anyone operating such a plant without a Certificate is liable to the penalties set forth in the Stationary and Hoisting Engineers' Act.

Application forms for obtaining STATIONARY or HOISTING Engineers' Certificates, may be had upon applying to the Chairman.

143-153 University Avenue TORONTO

BOILER INSPECTION

The Steam Boiler Act, Chapter 252 R.S.O., 1914, With Amendments Chapter 58—6, George V.

STEAM BOILERS.

All Steam boilers constructed for use in Ontario must be built from designs which have been approved and allotted a registration number by the Steam Boiler Branch.

Used boilers, boilers sold or exchanged, and unregistered boilers brought into the Province must be inspected prior to being put into operation.

Notice of repairs to steam boilers, stating the nature and extent of same, must be sent to the Steam Boiler Branch, and should such repairs be considered extensive by the Chief Boiler Inspector, the boilers will require to be inspected.

In each and every case the inspections must be made by Inspectors authorized to inspect boilers under the Steam Boilers Act, who are employed only by the Steam Boiler Branch of the Department of Public Works. Official certificates with the maximum working pressure stated thereon are issued to the owners of the boilers so inspected.

STEAM PIPING.

Drawings and Specifications of all high pressure steam piping must be approved and registered by the Steam Boiler Branch before any work of installation is commenced. The drawings submitted should show clearly the dimensions and layout of the main steam lines. Full particulars should be given as to the material used in the construction of the piping, and all valves and other fittings used in connection therewith must be of approved make.

Any deviation from the above requirements shall be deemed a violation of the Steam Boilers Act.

All communications in this respect should be addressed to the Steam Boiler Branch, Department of Public Works, Parliament Buildings, Toronto.

HON. F. G MACDIARMID, Minister of Public Works and Highways.

W. A. RIDDELL, M.A. Ph.D., Supt. Trades & Labour Branch

D. M. MEDCALF,

Chief Inspector of Steam Boilers.

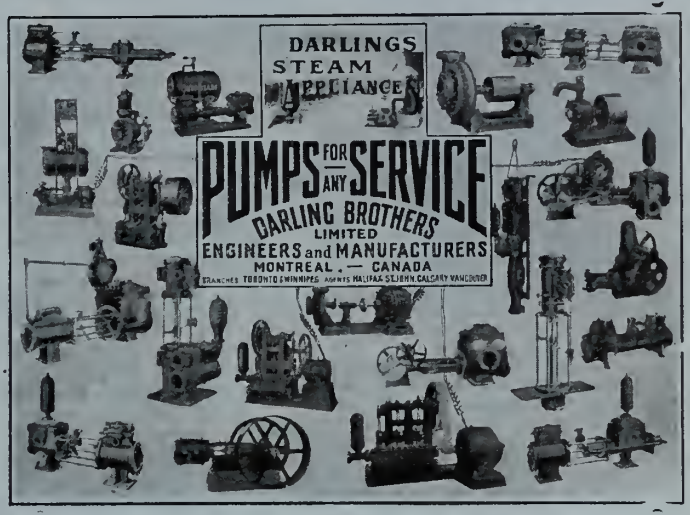
"Put it up to Darling Bros."

If you have trouble with your present system, or require anything new in steam appliances—put it up to "Darling Brothers"—let them solve your problems.

Their first quality steam appliances, plus many years of experience at solving troubles in the power plant, will make things go smoothly for you.

"Always tell Darling Bros. your troubles."



DARLING BROTHERS LIMITED, MONTREAL, P.Q.

Head Office and Works: MONTREAL

TORONTO WINNIPEG VANCOUVER

UEHLING WASTE METER

COMBINED

CO_2 AND TEMPERATURE RECORDER

Record of CO_2 and stack temperature on one chart.

Does your fireman know how much fuel he is wasting? Do you know?

The **Uehling CO_2 Recorder** makes a complete 24 hr. record of your combustion efficiency and the **CO_2 indicator at the Boiler Front** holds the fireman responsible.

Get more **Steam** per pound of **Coal** and reduce your annual fuel consumption.

Let us know the number and size of your boilers and coal consumed per year, upon receipt of which information we will be glad to send you full particulars.

CO_2 Indicator for Boiler Front

Let us hear from you. We are pioneers in the manufacture of Indicators and Recorders for Power Plant purposes.

Send for our Bulletin No. 110.

Uehling Instrument Company

2008 Empire Building New York City

PRECISION INSTRUMENT CO.

DETROIT - MICHIGAN

The 3-in-1 Gage for forced draft boiler installations is the standard equipment of to-day. It shows you at a glance the draft at the flue, the combustion chamber, and the ash pit.

PRECISION 3-in-1 Gage

Details on request.

"We were able to cut out one of our boilers—saving fuel and getting better results."

THIS STATEMENT from the Fenton Fibre Box Co., of N. Tonawanda, N.Y., is simply a repetition of similar claims received from several thousand other users of the simple and comparatively inexpensive

Morehead
Back to Boiler
SYSTEM

of steam line drainage and boiler feeding.

In this plant the returns from the steam heated corrigators, hot plates, etc.. were formerly collected in a hot well and pumped back to the boiler by the notoriously wasteful steam pump method.

With the Morehead System installed all water of condensation is returned to the boilers direct and under pressure as pure hot feed water requiring very little heat to again convert it into steam.

Result:—Hotter machines, faster and better work, operation of one boiler done away with, fuel saved and everybody pleased.

So thoroughly satisfied was this progressive concern with the Morehead System that they immediately installed a duplicate System in the Buffalo Box Factory which they own and control.

You can likewise convert your radiation losses into their equivalent of dollars. Tell us what you are doing and we will tell you —without obligation—what we can do for you.

Get the advice of our engineering department with our 25 years' experience in solving steam drainage and boiler feeding problems.

Don't buy that New Electrical Apparatus Just Yet

WE can supply you with high-grade apparatus that has been slightly used and discarded through no fault of its own, at an **immense saving in cost.** For instance, in many cases we take over entire plants simply because of changed conditions such as increased capacity, change of system, etc.

EVERYTHING IS OVERHAULED AND REFINISHED BY US AND **GUARANTEED** AS GOOD AS NEW, BOTH ELECTRICALLY AND MECHANICALLY.

Our catalogs of offerings should be in the hands of every power plant superintendent each time they are gotten out, and it will be worth while for anyone interested in this class of power plant equipment to be on our mailing list to receive **all** offerings.

Nearly all of the principal power, lighting and street railway plants in the United States are our customers.

WRITE FOR OUR LATEST CATALOG of **Power House Equipment, Street Cars, Motors, Hoists, Compressors, etc.**

MACGOVERN & COMPANY, Inc.

114 Liberty St., New York City

The Wrench of 25% Greater Efficiency

TRIMO PIPE WRENCH

Two new features have been recently added to the Trimo Pipe Wrench, namely Nut-Guards, in all sizes, and unbreakable steel frames, in leading sizes.

The Nut-Guards prevent the accidental rotation of the nut while in use.

These improvements add 25% to the usefulness of the tool.

The Trimo Pipe Wrench is made with wood handles in 4 sizes, 6-in., 8-in., 10-in., 14-in. and in steel handles in all sizes, 6-in. to 48-in. inclusive.

All Trimo Pipe Wrench parts are interchangeable.

The inserted jaw in the handle can be readily replaced when worn, thus adding to the life of the tool.

Nut with Nut-Guards

Inquiries from Importers and Dealers Solicited. Send for Catalogue No. 55.

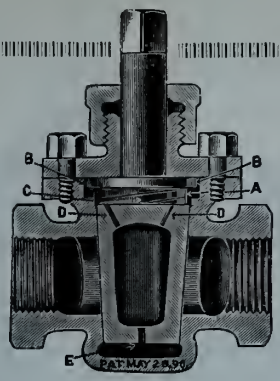
Ideal for Frequent Opening and Closing



Built to Withstand Extra Severe Service

HOMESTEAD
QUARTER-TURN VALVE

Simple to operate. Stands the strain of severest service. Tightness made certain by patented wedging cam that automatically forces plug downward in closing and instantly releases it again when handle is turned to open valve. The Plug is always held in perfect balance by means of special ports. Quick opening to full area is obtained by quarter-turn of handle.

MADE IN STRAIGHT-WAY, THREE-WAY and FOUR-WAY PATTERNS. SPECIAL VALVES FOR SPECIAL PURPOSES.

Drop a card for full details.

Homestead Valve Mfg. Co.

Works: Homestead, Pa. Pittsburgh, Pa.

CURTIS
Engineering Specialties

CURTIS Water Pressure Regulator

The Economy of this Curtis Water Pressure Regulator (See Illustration) lies in the fact that it greatly reduces the cost of keeping plumbing in order—This by obviating the wear and tear of water hammer or concussion in pipes.

This regulator is warranted to maintain the pressure desired, **with perfect uniformity, regardless of any fluctuations of outside pressure.** The workmanship and material of the Regulator **cannot be excelled.** Trouble from rust or clogging is **entirely avoided.** Delivery of water into service pipes at any desired pressure **is guaranteed.**

Send for special leaflet and price list to the manufacturers.

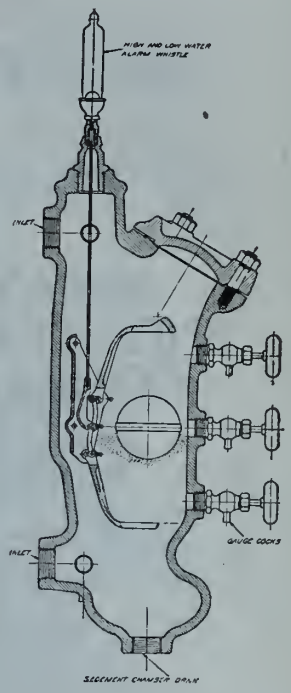
JULIAN D'ESTE COMPANY

26 Canal Street, BOSTON, MASS.

SAFETY CERTAIN

With High and Low Water Alarm

Exterior



Cross Section

The "Anderson" Safety Water Column

Safety first, safety last, safety certain all the time—that's the assurance that you get from the "ANDERSON."

Water in your boiler cannot rise above or fall below the danger mark without the WARNING WHISTLE OF THE "ANDERSON" giving the alarm.

POSITIVELY RELIABLE —Working parts cannot rust or stick.

Write for full details.

The V. D. Anderson Co.

1935 West 96th St., Cleveland, Ohio

If any advertisement interests you, tear it out now and place with letters to be answered.

SPRACO

COOLING SYSTEM

50% of the cost of installation is being saved yearly by plants which have dispensed with other cooling systems and adopted the "SPRACO." This should decide you in favor of the SPRACO SYSTEM, but that is not all; it's easier to operate and gives better satisfaction, besides making a big saving in power.

We guarantee that the Spraco System will be a success. We design the pond as well as furnish the nozzles. Ground and roof installations. Write for full data.

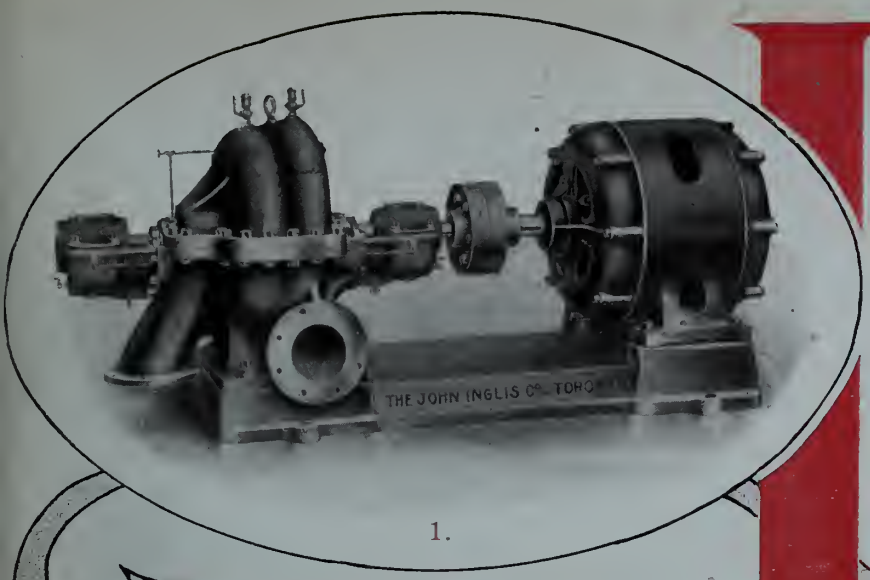
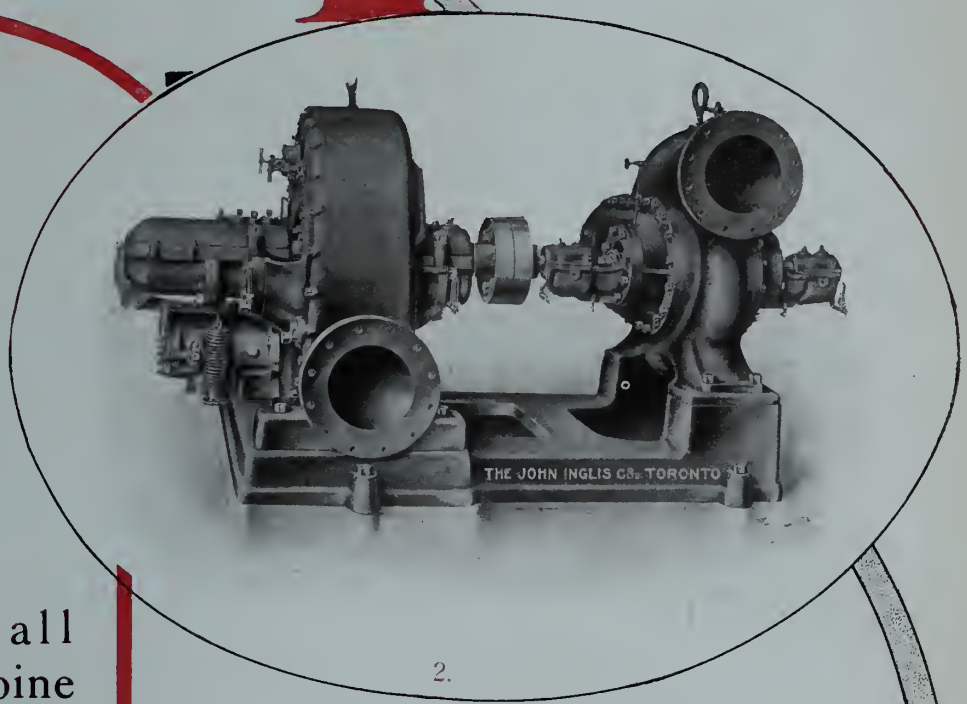
Inglis Turbine PUMPS



1.



2.

Oil ring bearings, hydraulic balance and water-cooled thrust bearings are standard for all "Inglis" Turbine Pumps.

Impellers and passages are highly finished, all working elements being carefully balanced against vibration.

Send us your inquiries.

Illustration No. 1 shows our Multi-Stage Split Case Turbine Pump for medium and high pressures. Direct connected to electric motor.

Illustration No. 2 shows our Double Suction Pump for Circulating low or medium heads. Direct connected to steam turbine.

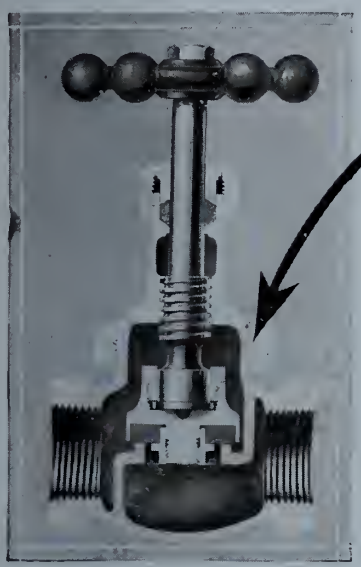
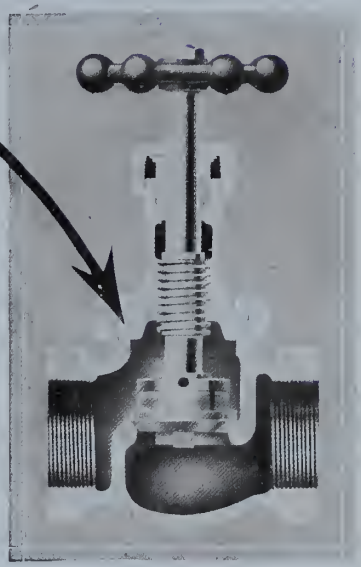
ALL PENBERTHY VALVES HAVE THE EXTERNAL THREAD CONSTRUCTION





COMPODISK

FOR

175 lbs. Steam Pressure

The Discs used in these valves will not crack or flake under high steam pressures or severe conditions.

Thousands in use giving the best of satisfaction.

MADE IN CANADA

The Arrows Show You
DO YOU REALIZE
What this Modern Improvement Means to Every Engineer?

SAFETY FIRST

When you tighten down the bonnet of a Penberthy Valve there is **no danger** of spreading or enlarging the bonnet end of valve body which causes a loose fitting and unsafe bonnet **because** the Penberthy bonnet fastens to the body by outside threads. It's a union connection so to speak. These threads being **away** from corrosive action of steam and water are always clean, and the body and bonnet do not "freeze" together. A Penberthy Valve is therefore easy to take apart without strain or injury.

You will never know all the valve comforts until you have installed "the Penberthy."

REGRINDING

FOR

200 lbs. Steam Pressure

Some of the largest plants in Canada where this type of valve is preferred use Penberthy Regrinding Valves exclusively.

They are made in Globe Angle, Cross and Horizontal Angle, Vertical and Swing Checks.

MADE IN CANADA

Manufactured by

PENBERTHY INJECTOR CO., Limited, Windsor, Ontario

RAINBOW

Over 50,000 engineers regularly specify RAINBOW, because it will make a tight joint that lasts for years.

RAINBOW has been used on every conceivable service in every industry. It's been tested so thoroughly that it is recognized as the standard sheet packing.

RAINBOW fits between the flanges like a mould. It is made of a compound that can't "burn" or "blow-out."

Start to use it to-day—you'll be more than satisfied.

SOLE CANADIAN DISTRIBUTORS

Waterous

Return Tubular Boilers

Combined with the advantages possessed in general by this type of boiler—economy in fuel consumption, large steaming capacity, ability to use hard and dirty water, and comparatively low cost — we can furnish you with a boiler setting that is designed and dimensioned to best handle the fuel you use.

We build Return Tubular Boilers up to 72″ x 18″. Most of these sizes carried in stock. If we cannot supply you from our yards we can turn out your order in quick time.

Let your next boiler be a "Waterous."

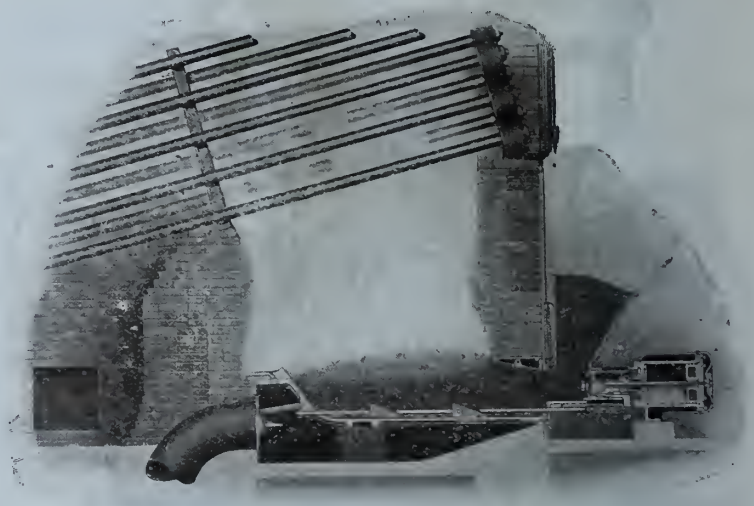
Don't Ponder

Save Money by Coming to a Quick Decision in Favor of

Jones Underfeed Stokers



Burns Less Coal and Cheaper Coal

Delay means lost money and it's not a ponderous question—it's **easy** to see the big advantage of installing a facility that will make a saving in fuel bills amounting to at **least 15% and often 25%**. Jones Stokers are doing it in every line of industry and they can do it for you.

Simple in construction but thoroughly efficient. No complicated parts to cause trouble. **No grates to lose coal through.** They respond instantly to load fluctuations and automatically maintain a uniform steam pressure.

If you are up against smoke regulations, the Jones Underfeed Stokers will keep you always within the law. Let us tell you all about them.

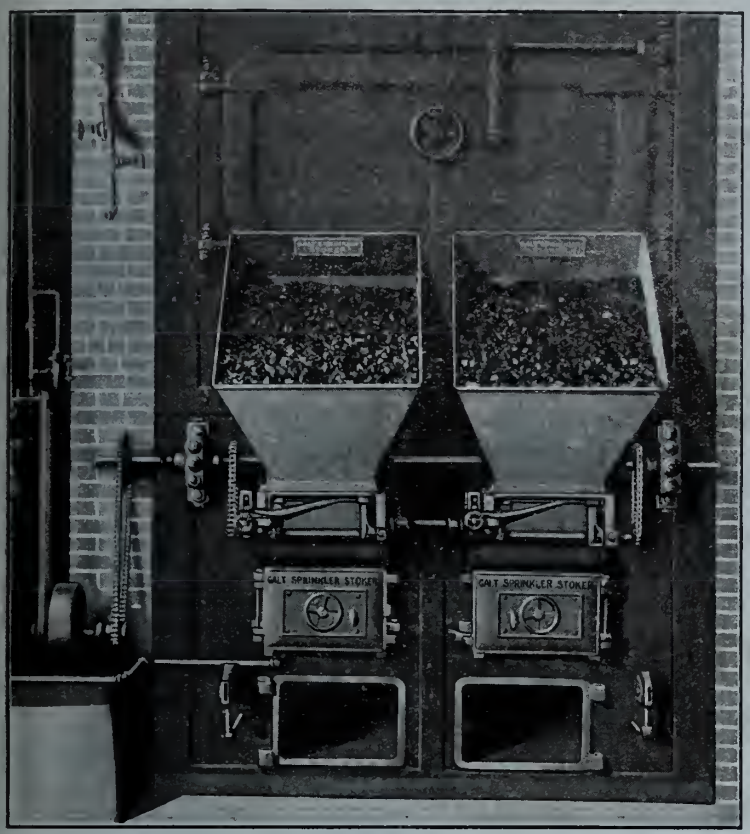
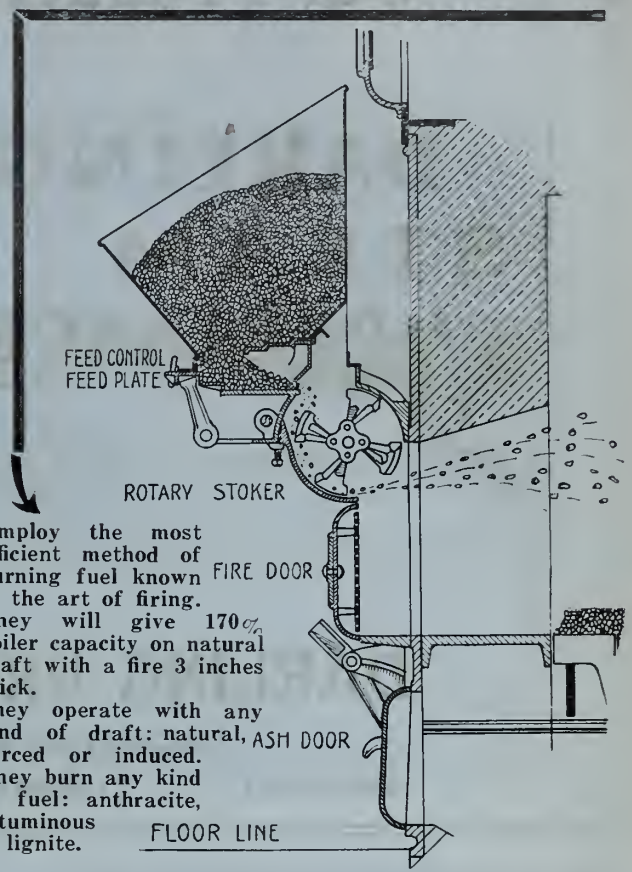
GALT SPRINKLER STOKERS



Two Type "A" Galt Sprinkler Stokers applied to 150 H.P. Return Tubular Boiler.
(Coal Hoppers immediately removable.)
Cost less than half of other stokers. Ask for prices.



Employ the most efficient method of burning fuel known to the art of firing.
They will give 170% boiler capacity on natural draft with a fire 3 inches thick.
They operate with any kind of draft: natural, forced or induced.
They burn any kind of fuel: anthracite, bituminous or lignite.

The Stoker mechanically feeds and perfectly spreads the fuel over the entire length and width of your present grates with the fire doors closed.

What Galt Stokers REALLY DO—

(1) Effect a saving in coal from 10% to 20%.
(2) Effect a saving in labor from 25% to 50%.
(3) Give a thin, brilliant, and perfectly level fire.
(4) Give smokeless combustion.
(5) Increase the boiler capacity greatly.
(6) Increase the percentage of the CO_2.
(7) Burn the fuel completely to finest ash.
(8) Operate for years without need of repair. And other important points.

We supply Power-Turbo Blowers, McNaughton Rocking Grates, Damper Regulators and other Power Plant Equipment.
Ask for our illustrated catalogues on Stokers, Grate Bars, etc., etc.

Announcement

It is barely two years since we occupied our big new plant. Yet the greatly increased facilities then placed at our command have been taxed to their utmost capacity. Hence, we have again been confronted with the problem of an additional increase of our manufacturing capacity.

In a measure, we anticipated this generous support of our many friends, and have been making preparations accordingly.

To-day, therefore, we are pleased to announce that we are now prepared, by added facilities to accommodate a substantial increase in production, and therefore solicit a larger share of your requirements. We take this opportunity of thanking you for past patronage, and look forward with pleasure to a continuance of same.

JOHNS-MANVILLE
Service to Power Plants

Increasing Power Output— by Reducing Friction

TO the engineer the very names "packing" and "stuffing-box" tell an interesting story. The sole function of rod packing is to prevent leakage. Until recently this has been accomplished, for a time at least, by filling the stuffing-box solidly with packing, screwing up the gland or allowing the packing to expand until its pressure on the rod was sufficient to hold back the steam or liquid attempting to escape.

This prevented leakage—but it cost money in three directions: heavy wear on packings, wear of the rod, and loss of power through friction. And the last is especially important if you consider that every foot-pound of energy consumed in plant operation directly reduces the surplus of power available for sale or for factory use.

So we set out to reduce friction and wear of rods and packings at no sacrifice of steam-tightness—and by solving the problem we have inaugurated a new era in "Stuffing-Box Engineering."

Johns-Manville Sea Rings are automatic and active, instead of inert. The pressure of the fluid against the packing holds the lip of the ring tight against the rod—and when pressure falls off or is on the opposite side of the piston, the packing relaxes and permits the rod to move freely. So friction is saved, and power—and the wear on packing and rod is less.

And Sea Rings are but one item in the standardized list of Johns-Manville Packings—a packing for every requirement. Each Johns-Manville Packing is different—with a sound engineering reason for the difference. They're designed to *wear*, and to save money and power—and we back each one to the limit.

You can prove it for yourself by investigation, almost anywhere, or by test—and we'll be glad to help you.

Merits of Some Recent Developments in Air Pump Design*

By E. Jones

In this paper there are discussed the merits of some of the more recent developments pertaining to a piece of equipment installed in most power stations. An air pump is a very essential part of the condensing plant, without which any of our modern steam-operated power stations or, indeed, any machines used for the generation of power, employing steam as the working fluid, would be practically of no value except for very small units.

IT may be advisable at the outset to run very briefly over the various types of condensing plant at present in use, in order to arrive at the cause of inventors turning their attention to the design of new types of air pumps. There are five types of condenser, viz., evaporative, ejector, barometric, jet, and surface.

Evaporative Condenser

Evaporative condensers are expensive because of the large cooling surface re-

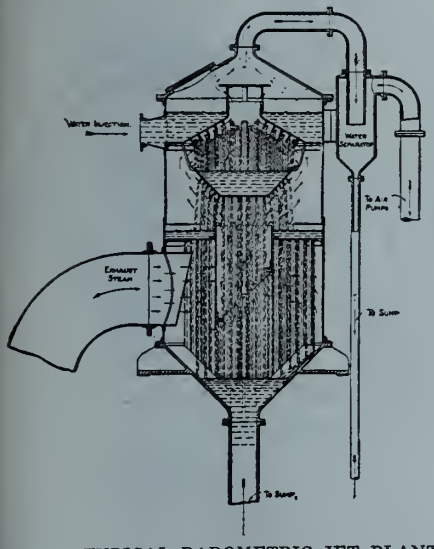

FIG. 1. TYPICAL BAROMETRIC JET PLANT.

quired to condense the steam, and are only adopted when it is almost impossible to obtain water which can be utilized for cooling purposes. Steam flows inside of the tubes, which are grouped together in sections, and all joined up to the header pipes or steam mains. Cooling is obtained by air, and the radiation effects caused by allowing a stream of water to continually pass over the tubes. There are a great many joints in the apparatus which tend to make this type of condenser unsuitable for modern requirements.

Ejector Condenser

The ejector condenser deals with the steam and air without the use of an air pump. The steam to be condensed is delivered into the condenser body, which is fitted with a specially designed series of nozzles. The cooling water enters under pressure at the top of these nozzles, condensing the steam and entraining the air and incondensable gases, the whole passing down the discharge pipe. Despite the simplicity of these condensers, they do not appear to have found general favor.

The foregoing types would appear to be still in the embryo stage, and open up large fields for further investigation.

Barometric Condenser

The barometric condenser is, of course, a jet condenser, in which the cycle of operations of the cooling water is just the reverse of the cycle used in the low-level jet plant—that is to say, the cooling water is pumped into the condenser and flows away by gravity down the tail pipe. It is, therefore, necessary to place this condenser at a height above the level of the water in the outlet sump, equal at least to the height of the water column which could be supported by the vacuum plus a marginal head of at least 3 ft. or 4 ft., to allow for pipe friction and to cause flow of the water. This very often means that the condenser has to be placed on the top of a building, or on a staging specially erected to accommodate it at the required height. Occasionally cases crop up where a barometric plant can be installed at the ground level of the engine room, but this means that the cooling water is at a level of at least 34 ft. below, and, therefore, if the pumping plant is of the centrifugal type, it is necessary to have a pump house considerably nearer the cooling water level, which means that the plant is not compact or self-contained. This is a decided disadvantage. Another point which does not tend to add favor to the barometric plant when placed at a distance above the exhaust branch of the prime mover is the long length of exhaust steam main,

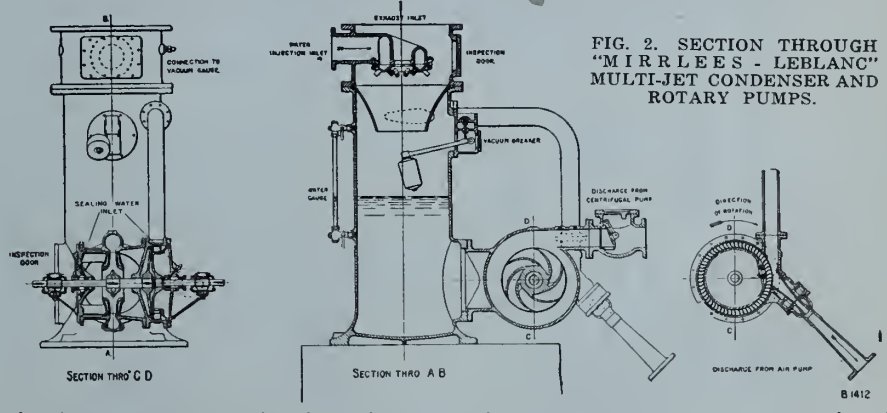

FIG. 2. SECTION THROUGH "MIRRLEES - LEBLANC" MULTI-JET CONDENSER AND ROTARY PUMPS.

which is not only expensive, but often a source of trouble, due to the greater number of joints, which have to be kept perfectly air-tight.

Low Level Jet and Surface Condensers

It is chiefly for these reasons that the barometric jet-condensing plant has been superseded by the low-level jet plant. At the present time the majority of condensing installations are either of the jet or surface type, and the choice generally depends on local conditions and sometimes by the amount of money available for the scheme on hand. With the low-level type of jet plant, the cooling water is drawn into the condenser which is under vacuum. The water and steam mix freely, and the latter is condensed, and the cooling water and condensate are extracted from the condenser by means of a pump which is invariably, as far as the writer's experience goes, of the centrifugal type, specially designed to meet the requirements of drawing water from a space under a very low absolute pressure and discharging at atmospheric pressure or against an external head. The air and gases which are not liquefiable under the conditions obtaining in the condenser, are dealt with by some type of dry air pump. The advantages of this type of plant over the barometric jet plant are that it can be placed immediately below the turbine, thereby reducing the possibility of air leaks. The whole equipment is self-contained and compact, and can be operated and regulated at very short notice by the engine-room attendant. Fig. 1 and 2, show a typical barmetric jet plant and low level multiple jet plant of the Leblanc type.

Surface Condenser for Marine Work

Perhaps the most important type of condensing plant is the surface condenser, inasmuch as it is used almost invariably for marine installations, and in a lesser degree for large power units, the reason for this being that the condensate is an important item, as it supplies a source of excellent boiler feed-water and also under the same external conditions, the power required to operate a surface condensing plant is generally less than for a jet plant. The design of modern

*From a paper read recently before the Institution of Engineers and Shipbuilders, Glasgow, Scotland.

surface condensers, as far as the condenser itself is concerned, has not changed materially for the last 30 years or so, so that there is no need to go further into details on this point. The cooling water is usually supplied by means of a centrifugal pump, except in cases where a syphonic action can be utilized or where the existing pumping plant is capable of taking care of the requirements of the condenser. A condensate pump is necessary to deliver the condensate from the condenser to the boiler feed-tank, and a dry air-pump to deal with the air and unliquefiable gases which find their way to the condenser. Alternately, an Edwards air pump can be adopted to deal with both the condensate and air If the disposition of the various parts of the installation demand it, a hot-well will also be required. The above table may be of interest in noting the relative costs and requirements of the last three types of condensers which have been considered.

Type of plant.	Consisting of—	Approximate net weight of apparatus.	H.P. required to drive condenser and auxiliaries.	Present day costs.	Equivalent ratio.
Barometric.	Condenser, staging, air-pump, injection pump, driving motor, switchgear, air and tail piping, main-exhaust piping and sluice valve, auto-exhaust valve. Complete erection.	40 tons.	89 B.H.P.	£2,700	1·286
Low-level jet.	Condenser, water-extraction and air-pumps, driving motor, switchgear, main sluice-valve, adapting and expansion pieces, auto-exhaust valve. Complete erection.	22 tons.	87 B.H.P.	£2,100	1·00
Surface.	Condenser, rotary air-pump, extraction pump and circulating pump mounted on common bedplate with driving motor and switchgear. Necessary interconnecting pipes, main exhaust steam-sluice-valve, expansion piece, adapting piece, automatic atmospheric-valve. Complete erection.	30 tons.	78 B.H.P.	£3,300	1·571

FIG. 2a. RELATIVE COSTS AND REQUIREMENTS OF THE FOREGOING THREE TYPES OF CONDENSERS.

The conditions which have been assumed are the same for each case, and are as follows:—Steam quantity 40,000 lbs. per hour, vacuum 28½ inches (barometer 30 inches)—95 per cent. of the barometer, cooling water 60 deg. Fah., prime mover, high pressure steam turbine. For the barometric plant, .25 inch has been added to the vacuum to allow for the drop between the turbine-exhaust flange and the condenser. It should be noticed here that under the present abnormal conditions, surface condensers are in a practically unfortunate position, owing to the cost of the materials used for the tubes and tube plates, which is approximately 27½ per cent. of the value of the whole equipment. The price of tubes to-day is 38 cents per lb., whereas, in 1914, just prior to the commencement of the war, the price was 15 cents per lb., so that the increase in the cost of tubes is 240 per cent., and the increase in the cost of plates is approximately the same. Therefore, if times were normal, surface-condensing equipment would appear in a much better light, and although it is not proposed to suggest an accurate figure for surface plant with tubes at 15 cents, it is clear that a reduction of from $2,500 to $3,000 should be possible in the case given above. This would bring the cost ratio of the surface plant, when compared with a multi-jet plant, from 1.57 to about 1.3.

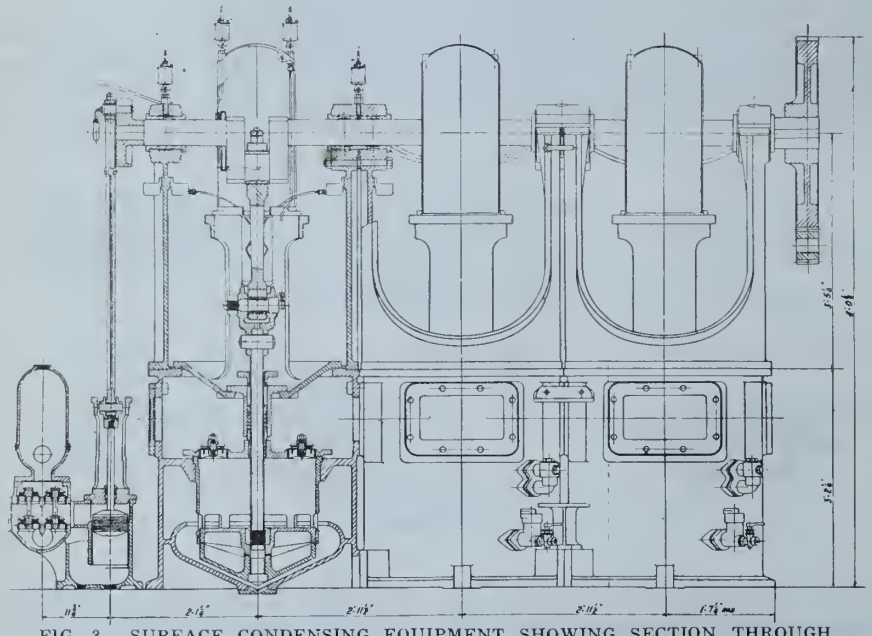

FIG. 3. SURFACE CONDENSING EQUIPMENT SHOWING SECTION THROUGH "EDWARDS" AIR PUMP.

With the earliest types of surface condensing equipment, it was usual to use one pump for removing both the condensate and air from the condenser. This pump was known as a "wet" air pump, and a good example of this type is the Edwards air-pump, one of the most efficient of its class. It is shown in section in Fig.3. The chief advantages of this type of pump are:—Low power required for driving; positive action and consequent stability; ability to cope with excessive air leakages. While the Edwards pump is still an excellent pump for units up to say, from 3,000 to 4,000 k.w., it must be remembered that, with the ever-growing size of power units, its disadvantages should be kept in view. For large units with Edwards pumps, it is necessary that they should run at a very low speed, and consequently they are very cumbersome, and take up a large amount of floor space. With jet plants, the Edwards pump is sometimes used as a dry air-pump. It is necessary, of course, to provide a small quantity of water for sealing purposes. Volumetric efficiency in this pump varies considerably with the degree of vacuum required, and decreases as the vacuum increases from about 50 per cent. at 3½ inches absolute pressure to 18 per cent. at 1 inch absolute pressure.

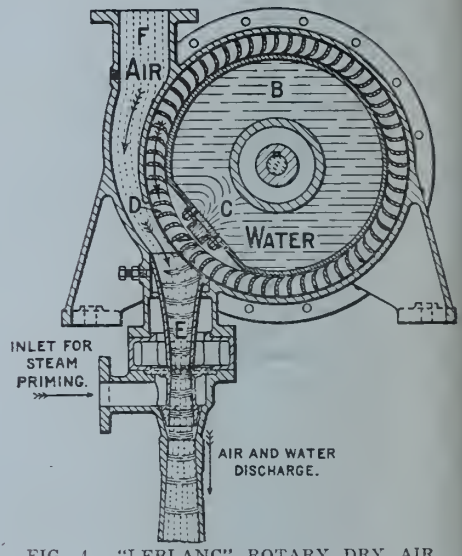

FIG. 4. "LEBLANC" ROTARY DRY AIR PUMP.

Dry Air Reciprocating Type Pump

Another system is that in which a dry air-pump of the reciprocating type is used to remove the air and uncondensed gases, and a separate pump to remove the condensate. The advantages and disadvantages of this system are the same as for the Edwards air pump, but the efficiency is rather better. Previous to the introduction of the steam turbine, condensing plant equipments were furnished with air pumps of one or other of the types mentioned above, but as soon as the turbine became a commercial pro-

position, it was necessary to look for a type of pump having features specially adapted to its requirements. With turbine installations, it is essential to use a high vacuum in the condenser, whereas

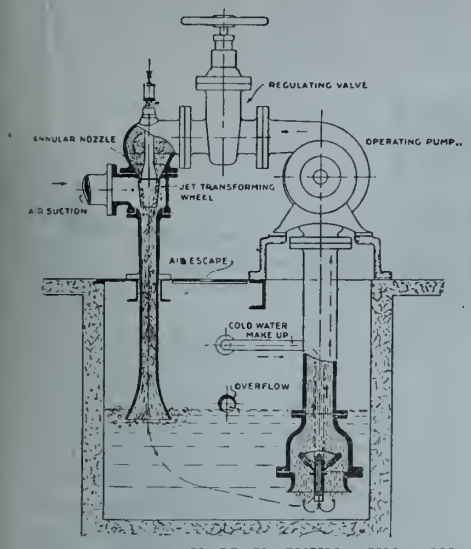

FIG. 5. HYDRAULIC VACUUM PUMP ON EJECTOR PRINCIPLE.

with steam engines of the reciprocating type a vacuum of more than 26½ inches was seldom required. In fact, it is questionable whether using a higher vacuum than 26½ inches would not be considered a disadvantage. With the turbine, however, a vacuum less than 27 inches is rarely asked for, and sometimes the specified figure is as high as 29.25 inches with the standard barometer reading of 30 inches.

In considering these figures, due allowance must be made for the altitude of the place. The most economical vacuum for a turbine installation depends on a variety of things, and each case has to be considered on its merits. On reference to steam tables it will be seen that an increase in vacuum from 27 inches to, say, 29 inches, other conditions as air leakage remaining the same, necessitates an increase in the capacity of the air pumps from 1.00 to 3.25, which for a large installation with Edwards or reciprocating dry air pumps is a very serious

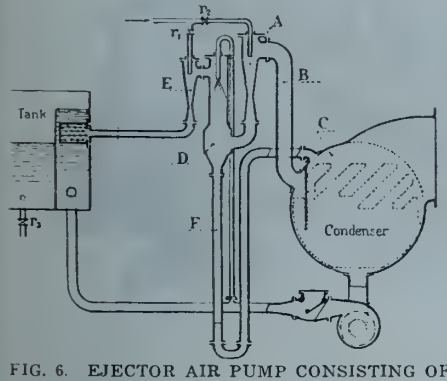

FIG. 6. EJECTOR AIR PUMP CONSISTING OF TWO EJECTORS WORKING IN SERIES.

matter. Hence it is that various types of rotary pumps, which are specially suitable for dealing with large volumes of air at low tension, have been designed since the adoption of the steam turbine, several of which have proved very successful. The general design of these pumps is much the same, in so far as they use a certain quantity of what is termed "operating water," for which various devices have been invented to cause this water to move in such a manner as to entrain the air from the condenser and discharge it to the atmosphere.

Leblanc Rotary Dry Air Pump

Perhaps one of the best known rotary dry air-pumps is the one invented by Prof. Maurice Leblanc. It has been used to a very large extent all over the world and its action is shown in Fig. 4. This pump is capable of maintaining a very high vacuum, and for this reason, coupled with the fact that it is very simple in construction and not likely to get out of order, it has been largely used

The power required to drive these pumps is rather higher than that required for an Edwards or other good type of reciprocating air-pump, and consequently a good deal of attention has been paid recently to another type of pump which would incorporate the simplicity and compactness of the rotary pump and the low-power consumption of the Edwards and other reciprocating pumps. The general trend of thought seems to have been in one direction, and there are now on the market, and in commercial use, air-pumps operating on the ejector principle. Nearly all the leading condenser manufacturers now construct air-pumps of this description.

for turbine installations. It cannot be claimed for this pump—or indeed for any type of rotary air-pump—that it can successfully deal with an excessive air leakage, but consideration will show that this quality is not essential in the case of turbine installations where air leakage is reduced to a minimum by the adoption of steam or water-sealed glands where the shaft passes out of the turbine casing. With a surface-condensing plant, it is only possible for air to be brought into the system by the feed-water and carried over with the steam, or by leaking in at the joints. With jet plants, the air brought in with the injection water has to be allowed for in addition to the above, and it is for this reason that the air-pump on a jet plant requires to be larger than that for a surface-condensing plant doing the same steam duty.

the ejector principle, as illustrated in Fig. 5, which consists of the injection head, the air - suction chamber, the rotary wheel, and the throat and tail pipes. The operating water passes between two nozzle rings, and the cone of water passes between the body of the wheel and the outer sleeve, impinging on the inclined surfaces of the vanes, thus imparting a rotary motion to the wheel. To operate the pump, it is necessary to provide a certain amount of sealing water, which is supplied from a tank situated as convenient as possible to the pump. The sealing water takes up a certain amount of heat from the air and water vapors withdrawn by the air-pump, and a piping arrangement is provided for withdrawing a certain amount of this water by means of a by-pass connection on the operating pump discharge,

this by-pass being fitted with a controlling reflux valve. The quantity of water withdrawn in this manner is replaced by make-up water drawn from the circulating inlet piping or an independent supply, thus cooling the water used in the cycle of operation. This apparatus is doing regular service on one of the turbo-alternator groups at the Glasgow Corporation power station at St. Andrew's Cross. A number of installations have also been supplied to other concerns.

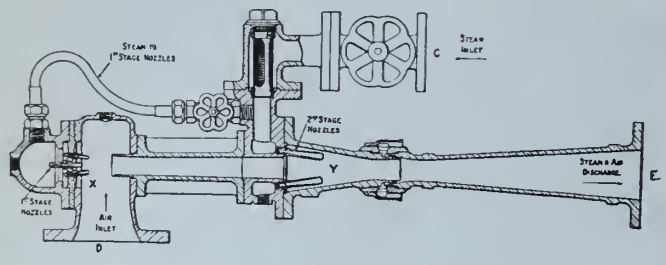

FIG. 8. "LEBLANC" EJECTOR AIR PUMP—SECTION 1.

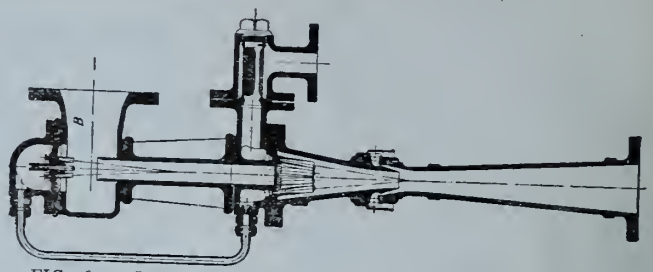

FIG. 9. "LEBLANC" EJECTOR AIR PUMP—SECTION 2.

Willans-Muller Ejector Air Pump

Willans & Robinson, of Rugby, manufacture the Willans-Muller ejector air-pump, which is operated by the circulating water, either on the series or shunt system. With the series system, the whole of the circulating water passes through the ejector before entering the condenser. With the shunt system, only a portion of the cooling water passes through the ejector, which, after use, is returned to the pump suction or the source of supply. A third method of operating this ejector is by the separate pump system, in exactly the same manner as described with reference to the Worthington pump. The Glasgow Corporation have a set of this apparatus at work at Pinkston Power Station, and good results have been obtained, and a second set is just being installed at St. Andrew's Cross.

Hick, Hargreaves "Ejectair"

Another type of ejector air-pump is that manufactured by Hick, Hargreaves & Co., Bolton, under license from the Maison Breguet, Paris, which is really two ejectors working in series with an auxiliary condenser placed between the first and second stage of the ejectors. A number of these air-pumps, termed "Ejectairs," have been supplied or are under construction for the French navy. Referring to Fig. 6, it will be observed that the primary ejector is placed in direct communication with the main condenser, and extracts the aerated vapor, being operated by a single steam jet or nozzle. The mixture of steam and partly compressed vapor is then discharged to the auxiliary condenser, and the water returned to the main condenser to be dealt with by the extraction pump. The second stage ejector is coupled up to the auxiliary condenser, and draws the air away, discharging it to the feed-tank. An automatic air-inlet valve is fitted to the auxiliary condenser, to regulate the absolute pressure therein. It is claimed that taking air from the atmosphere in this manner materially assists the stability of the plant, and also renders it more flexible.

These ejectairs are designed for working with steam pressures at 55 lbs. per square inch or above, and, with a special arrangement of nozzles, lower pressures can be used in the primary ejector, although the advantage of this is not apparent if it is impossible to work the other ejector under the same conditions, neither is it clear whether this can be accomplished or not.

The curves, Fig. 7, show the performance of an ejectair. Steam to the ejectors had an absolute pressure of 125 lbs. per square inch, and the steam consumption is given as 194 lbs. per hour, of which 129 lbs. are recoverable. The apparatus, worked in conjunction with a small jet condenser, dealing with 94 gallons of injection water per minute.

Curve 1 gives the vacuums obtained with water leaving the condenser at a temperature of 91.4° Fah. (33° C.), and the auxiliary condenser out of action; Curve 2 the volume of air dealt with in cubic feet per hour; Curve 3 the vacuums obtained with given air leaks, and the water leaving the main condenser as for Curve 1, but with the auxiliary condenser supplied with cooling-water at 66.2° Fah. (18° C.), and Curve 4 the volumes of air dealt with under the same conditions. It was caluculated that the air coming in with the injection-water and at leaky joints amounted to 1.10 lbs. per hour (.5 kg.).

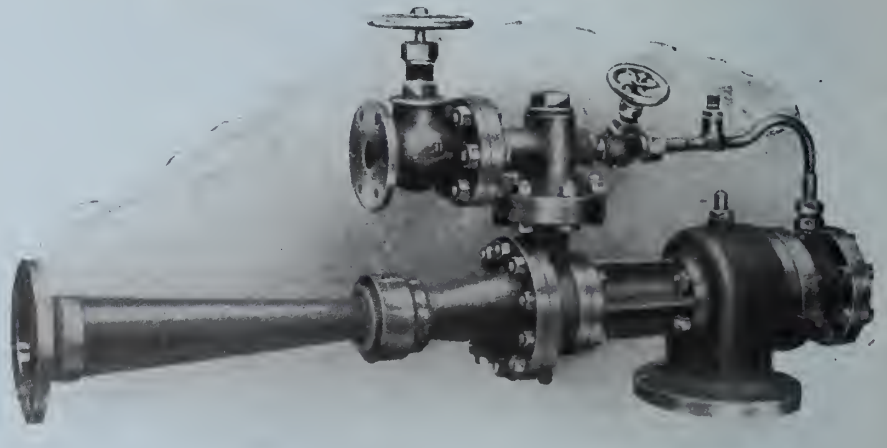

FIG. 10. "LEBLANC" EJECTOR AIR PUMP—EXTERIOR VIEW.

Leblanc Ejector Air Pump

The British Westinghouse Electric & Mfg. Co., Manchester, and Mirriless Watson Co., Glasgow, manufacture an ejector air-pump, under license from the Societe Anonyme Westinghouse, Paris and Le Havre, which is another invention of Monsieur Maurice Leblanc. It is the outcome of many months of arduous research work, during which time innumerable difficulties were surmounted by the inventor, with the result that a really first-class ejector air-pump has been evolved. Figs. 8, 9 and 10 show the general layout of the apparatus.

The pump is arranged to work in two stages, and the steam is admitted to the second stage of the ejector by opening the stop valve. Immediately it is opened, steam fills the annular space behind the nozzle plate, and finds its way into the throats of the group of nozzles attached to this plate; it then passes along the steam pipe which supplies the first-stage nozzles, which are also attached to a nozzle plate. The supply of steam in this set of nozzles is controlled by the stop valve on the steam-supply pipe. The pump is connected to the condenser at the branch, which is the air-inlet branch.

At the entrance to each of the steam spaces, fine wire-gauze strainers are fitted to prevent any foreign matter which may have primed over with the steam from the boilers, from entering the nozzles, thereby intercepting any stoppage in the nozzle throats, and consequently a loss of vacuum. These nozzles are efficiently locked to the nozzle plates. The mixture of air and steam is discharged at the mouth of the divergent cone, and led away to the boiler feed tank, so that the heat units contained in the operating steam can be reclaimed by heating the feed-water. To start the pump to work, it is only necessary to open up the steam valve, and the vacuum will at once commence to increase in the condenser or other vessel to be evacuated. When the vacuum gauge becomes sta-

tionary, the second-stage steam-inlet valve is opened up to bring the vacuum to a maximum. A very important feature in this pump is the absence of moving parts. The simplicity of the apparatus is even more remarkable than that of the Leblanc rotary pump.

Advantages of Ejector Air Pump

The advantages claimed are as follow:—Extreme simplicity; the small amount of energy required for operating purposes; the high efficiency obtained; ease with which starting can be effected, and the small amount of attention required whilst at work; ability to produce the highest possible vacuums; stability. In scanning these claims we can pass over the first, which has already been mentioned and is obvious; there are simply two steam valves to open. The second deserves some consideration. The operating steam in passing through the nozzles decreases in pressure, and consequently in temperature, and also, after passing through the nozzles, does work in accelerating the velocity of the air, increasing its temperature and compressing it. There is also a small amount of heat lost, due to friction in passing through the diffuser portion of the ejector, which might be considered negligible. Beyond this, the whole of the heat in the steam can be utilized to heat up the boiler feed-water, and in order to obtain full benefit from the apparatus, it is highly desirable to use the discharge from the ejector for heating purposes of some description. Thus, both the steam and air can be made to do useful work. In view of this, it must not be forgotten that when an ejector of this type is specified as requiring so many pounds of operating steam per hour, this is only the apparent quantity, the actual quantity is really far less, since the great majority of heat units in the steam are still available for further work. The actual heat units recovered can easily be calculated from steam tables, since it is known that the steam and air leave the ejector at a pressure of from 10 to 12 lbs. per square inch by gauge.

Auxiliary Condenser Not Required

It will be observed that with a Leblanc multijector, an auxiliary condenser is not required, and in this respect it differs materially from the "Breguet" ejectair. The employment of an auxiliary condenser has the disadvantage that the total heat units of the steam used in the first-stage ejector, which amount to an appreciable percentage of the total heat units used on the whole apparatus, are dissipated and lost. The makers give this percentage as about 33. Another reason for dispensing with the auxiliary condenser will be apparent from the following:

In all steam-operated ejectors, one of the difficulties that have to be contended with is the fact that the steam leaves the nozzles at a velocity varying from about 3,000 to 3,600 feet per second, while the velocity of the fluid to be entrained is practically nil. This is the cause of considerable loss of efficiency in any ejector, but if an auxiliary condenser is used, the defect is doubled, because the velocity of the fluid to be entrained, which has been imparted to it by the operating steam during its passage through the first-stage ejector, is dissipated and lost as soon as it enters the condenser. The cooling water used on the auxiliary condenser has to be dealt with by the condensate pump, thus increasing the power absorbed by the plant. When working with surface condensers this water must be of good quality, as it has to be returned to the boilers.

The third claim relates to efficiency. It is well known that ordinary single-stage

FIG. 11. STEAM NOZZLE DIAGRAM.

ejectors only work well when the compression ratio is as 1 : 7, and it is partly for this reason that the Breguet Co. have introduced the auxiliary condenser, so that the vacuum obtaining in this condenser is about 25.6 inches with the barometer at 30 inches, the compression being approximately as 11 : 76, or roughly, 1 : 7. The overall efficiency of this plant is, therefore, apparently still further reduced, because air is admitted from the atmosphere into the auxiliary condenser which is under a vacuum of 25.6 inches, and this, together with the air from the condenser, has also to be ejected by the secondary ejector to the atmosphere.

When Professor Leblanc set out to design his ejector he foresaw the possibility of using an intermediate condenser, but he also appreciated its disadvantages, and decided to do without it if at all possible. At the same time, he knew that it was essential to use two stages in order to get a stable and efficient ejector. With this end in view, certain steam nozzles were designed on the lines of the formulae of Professor Rateau, and the action of the steam issuing from these nozzles when under high vacuum was directly observed. The result is shown by Fig. 11. The steam issuing from the mouth of the nozzle expands and contracts alternately, ultimately assuming a section of constant area. It was found that a number of these nozzles grouped together gave far better results than a single nozzle of the same throat area as the group of nozzles.

Number and Size of Nozzles

The reason for this is to a large extent due to the fact that the alternate increasing and decreasing of the cross sectional area of the steam stream is minimized by the contact of one steam stream with the next, when groups of nozzles are employed, and this helps to considerably increase the surface available for the entrainment of the air and gases. This entrainment is carried on mainly by friction, and it will be seen that if an appreciable amount of gas has to be dealt with the frictional surface exposed to the gas has to be as large as possible. It is also inversely proportional to the density of the gas or fluid. The number and size of the nozzles depends entirely on the space available in the diffuser, and keeping within the limits of workshop practice.

The smallest number employed by the Mirrlees Watson Co. is three, each of which has a throat diameter of 1 mm. These are first-stage nozzles. On the largest size of pump, and in the second stage the number of nozzles is 30, and these have a throat diameter of 5.2 mm., when using operating steam at 90 lbs. per square inch. Professor Leblanc, in his paper of 1911 to L'Association Technique Maritime, says that "the operating steam entrains the air by friction. During entrainment it is the velocity of the steam which is utilized. and not its kinetic energy." Calling M the weight of operating steam used per second, V its velocity at the outlet of the nozzles, m the weight of air drawn in per second, and W the velocity of the mixture of air and steam, then—$MV = (M + m)\ W$.

The ratio of kinetic energy, $\frac{mW^2}{2}$ of the air drawn into the kinetic energy, $\frac{MV^2}{2}$ contained in the operating steam as it comes out of the nozzles, can, therefore, be stated as

$$\frac{m\,W^2}{M\,V^2} = \frac{m\,M}{(M+m)^2}$$

so that when $\frac{m}{M} = 1, \frac{1}{2}, 1\text{-}3, \frac{1}{4}, 1\text{-}5.$

$$\frac{m\,M}{(M+m)^2} = .25, .222, .187, .160, .139.$$

This shows that if the utilization of the kinetic energy is to be the basis of the design, then for maximum efficiency it is necessary to bring the ratio

$$\frac{\text{Air dealt with}}{\text{Operating steam used}}$$

as near to unity as possible.

M. Leblanc continues:—"We tried to diminish the loss of kinetic energy by producing at the entrance of the diffuser a higher vacuum than was necessary, so that the fluid drawn in came in contact with the operating steam with a considerable velocity. If the efficiency of the diffuser could be brought almost to unity, we could add considerably to the over-all efficiency, but this has been found to be impracticable. Following on this, it was suggested to use puffs of steam after the manner of steam coming out of locomotive chimneys, but the complications involved in making arrangements for stopping the inlet of air during each puff were such that it would have been easier to use a centrifugal compressor. Afterwards we tried to compensate for the bad efficiency due to frictional entrainment by transforming heat into kinetic energy in the nozzles. Superheating the operating steam, although so useful for turbine work, is, however, not good for an ejector, because it is more difficult to effect compression in the diffuser which outweighs the advantages obtained in the nozzles. The next scheme was to use hot water in the nozzles, but this likewise proved unsuccessful."

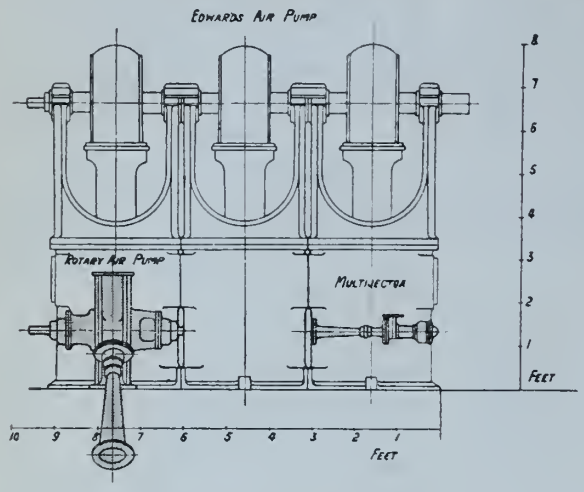

FIG. 12. RELATIVE SIZES OF "EDWARDS," ROTARY, AND MULTIJECTOR AIR PUMPS FOR SAME STEAM DUTY. WEIGHTS 20,832 LBS., 4,480 LBS., 97 LBS. RESPECTIVELY

Entrainment by Friction

After numerous other trials, it was decided that entrainment by friction was most economical, and various types of diffusers and different groupings of nozzles were experimented with, until the present ejector, as shown in Figs. 8, 9 and 10, was decided to be the most suited for condenser work. To go through the various stages in detail which led up to this design would take up too much time. With the form of ejector adopted, it has been found that the efficiency of the nozzle is on an average 85 per cent., whilst that of the diffuser is 70 per cent. It will be seen that this ejector agrees very well with the ideal ejector which Prof. Leblanc had in his mind. The first stage, which consists of a small group of nozzles, serves a triple purpose, inasmuch as it effects a certain amount of compression, heats up the entrained air, and gives it considerable velocity, and consequently an increase in momentum. The second stage has a larger number of nozzles, and it is here where the major portion of the work is done, the air being compressed from approximately 26 inches vacuum up to something more than atmospheric pressure. To be more accurate, the steam used in the first stage is about 5 per cent. of the total.

High Vacuum Results

In support of the fourth advantage which this air-pump is supposed to possess, the following figures were obtained on the French torpedo-destroyer Boutefeu. The turbines were stopped, but steam was on the glands. The volume to be evacuated was about 635 cubic feet. After one minute, the vacuum was 6 5-16 inches, two minutes 15 inches, three minutes 22 13-16 inches, four minutes 25 9-16 inches, five minutes 26¾ inches, and six minutes 27 9-16 inches. The theoretical vacuum corresponding to the temperature of the water 67.1 deg. Fah., viz., 28¼ inches, was attained in 11 minutes. It was also arranged later to allow certain known air leakages to enter the condenser. With a 5 mm. nozzle which passes 36.2 lbs. of free air per hour, the vacuum dropped only ⅜ inch. With a 15 mm. nozzle, which is equivalent to 326 lbs. of air per hour, the vacuum was 21¼ inches. With an inch cock full open it took 11 minutes for the vacuum to fall to 12¼ inches, at which figure the mercury column remained steady. On closing the regulating valve below the nozzle, the vacuum at once rose and attained the maximum almost immediately.

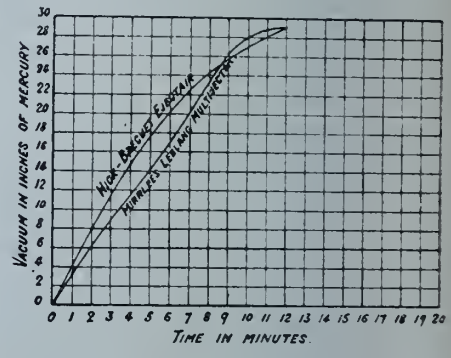

FIG. 14. DIAGRAM OF TIME TAKEN TO START UP A "HICK-BREGUET" EJECTAIR, AND A "MIRRLEES-LEBLANC" MULTIJECTOR.

There is a central station near Glasgow where this type of apparatus is at work with a multi-jet condenser. Sometimes when changing machines they are liable to partially lose their water for a minute or so, but none of the staff ever have to trouble about the ejectors for, as soon as the water comes back again, the vacuum at once builds up, and the set is never shut down through failure of the air-pumps. As a matter of fact, in the case above stated, it is highly probable that during the period that the water supply to the condenser is very small, there is an air passage between the water spaces of the other condensers in the station and the multi-jet plant which would allow of a very excessive quantity of air getting into the condenser on load. This also shows that stability, the sixth claim, is another salient point.

That high vacuum can be obtained is proved by the fact that this apparatus is now being used in the French navy and mercantile marine, as well as on some land installations for refrigerating pur-

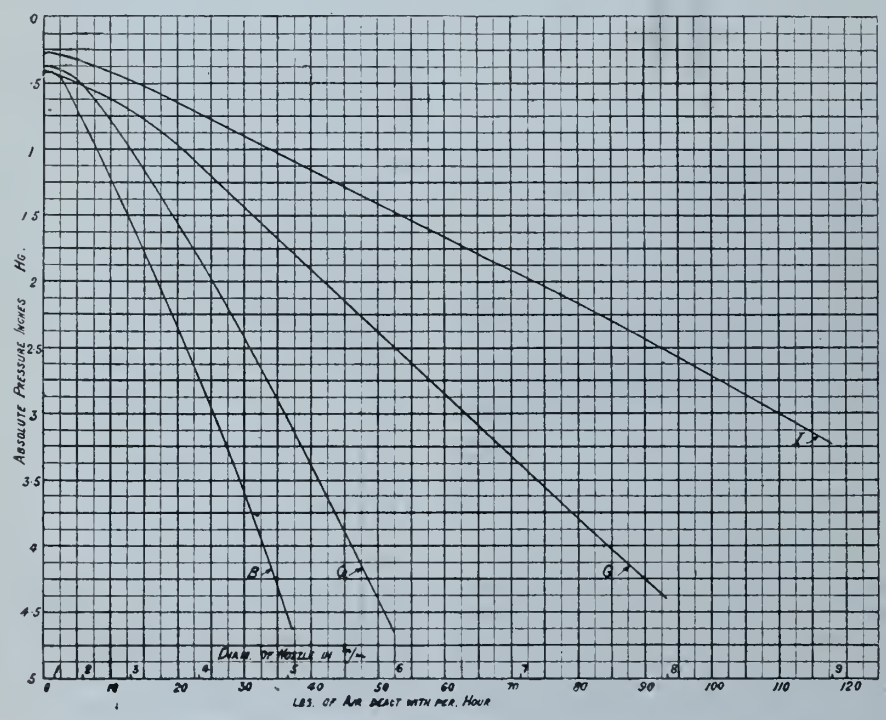

FIG. 13. AIR DEALING CAPACITY OF VARIOUS "MIRRLEES-LEBLANC" MULTIJECTORS.

poses, and installations are at work where the maximum vacuum obtained is within 1 mm. of the barometer. For condenser work the best results obtained so far by the French Westinghouse Co. are within 5 mm. of the barometer. From the foregoing remarks it would appear that this type of air-pump is ideal for use on board ship, and particularly in the navy, where space is so valuable and weight of such consideration. To illustrate this point, Fig. 12 has been produced, and represents to the same scale an Edwards' air pump, Leblanc rotary air pump, and Leblanc multijector for a steam duty on a surface condenser of 40,000 lbs. per hour, with water at 60 degs. The vacuum 28½ inches, and barometer 30 inches. The weights are approximately 20,832 lbs., 4,480 lbs., and 97 lbs. respectively. For land work it is equally suitable, and will soon supersede the rotary pump in many power stations. For sugar refineries, chemical, and other allied works it should prove exceptionally attractive, and take the place of many reciprocating dry air-pumps, particularly as in such factories the exhaust steam can generally be utilized to the fullest advantage on other processes. It may be advisable to point out here that this pump is purely a dry air-pump, so that for surface condensers as additional water or condensate extraction pump is still required, and for jet plants, the usual extraction pump.

No. 18 M. J. Condensing Plant with motor-driven Water-Extracting Pump, 1-Size "G" and 1-Size "I" Multijector Air-Pump installed at the Scottish Central Electric Power Co., Ltd., Bonnybridge.

OFFICIAL TEST DATA OF "MIRRLEES-LEBLANC" MULTIJECTOR AIR PUMP.

Fig. 13 shows the aid-dealing capacity of various sizes of multijector pumps taken from the actual tests. The maximum vacuum in each case is equivalent to the theoretical, the slight difference at the origin of the curves being due to the different conditions under which each pump was tested.

The Table of Tests is taken from a plant installed at the Scotish Central Power Station at Bonnybridge at a date six months after the plant was put on commercial load. This Company have just decided to order another plant, and have specified Mirrlees-Leblanc multijector air-pumps.

Fig. 14 shows the time taken to start up a Hick-Brequet ejector and that of a Mirrlees-Leblanc multijector.

Figs. 15 and 16 show an application of Leblanc ejectors for refrigerating purposes. The arrangement is that supplied for magazine cooling on the French cruiser "Souffren."

There is no doubt that considerable improvements have been effected in air-pump design during the last few years, nevertheless there is still room for much further progress, and it is to be hoped that when hostilities cease and the British engineer has time once again for research work of this nature we shall have to drop all our present-day notions of efficient air-pumps for a type which will compel all others to become obsolete.

POWER PLANT OPERATION AND MANAGEMENT

TO obtain the greatest efficiency possible in a power plant is not only a matter of design, but a good deal a matter of proper operation and management. Most power plants could make large savings in this way, and there are exceptionally few where some improvements could not be made without spending a dollar for new equipment. To obtain full benefit from the equipment on hand, the men operating it must be made more efficient, and this can be done by education, strict supervision, pay according to merits (bonus system), competition and advancement, welfare.

Education, while the most important, is also the most neglected factor in economic operation of a power plant. This is especially true in the boiler room where the waste is greatest. Skilled labor should be employed. Ordinarily, anyone is hired who will work for low wages and maintain the steam pressure. Every boiler room should have a man with authority to give orders and with sufficient personality to have his orders respected. This man should predetermine by the proper use of various instruments, the most economical ways of burning coal and instruct the firemen as to the best methods, and then insist that these methods be carried out.

FIG. 15. APPLICATION OF "LEBLANC" EJECTORS FOR REFIGERATING PURPOSES.

FIG. 16. APPLICATION OF "LEBLANC" EJECTORS FOR REFRIGERATNG PURPOSES.

Jointly with extending the license laws and making examinations more strict, opportunity should be offered to men intending to become operating engineers to acquire the necessary knowledge. While the practical part can be learned in the power plant directly, the fundamentals of theory which are all important to the up-to-date operating engineer are difficult to obtain properly. Co-operation of educational institutions is needed by the forming of classes at the various universities and other schools to give courses on economic operation of power plants. Instruction should be given by correspondence to those unable to attend in person.

VOLCANIC STEAM POWER

By D. Street.

THE harnessing of volcanic heat to industrial purposes is an idea that has often presented itself to the visionary mind, but it needed the war to bring the project into the realm of commercial actuality. The price of coal in the inland towns of Italy has now reached the fantastic level of $50 a ton, and, in consequence, attention has been turned towards other possible sources of power.

In Central Tuscany, as is well known, there are numerous cracks in the ground from which jets of steam spout high in the air with great force and constancy. As far back as 1903, tentative experiments were made with a view to using this steam for the generation of power. Holes were bored in the ground down to the source of the steam, which is a hard stratum of rock about 300 to 500 feet below the surface. These bore-holes which are lined with iron pipes and vary from 15 to 20 inches in diameter, were found to yield steam with a pressure of 2 to 3 and exceptionally up to 5 atmospheres, at temperatures varying from 150 to 190 deg. C. For several years these jets have not been diminished in their capacity nor does a new boring seem to interfere with the preceding ones, provided the distance from one to another is not less than 50 feet.

Method of Application

In a recent communication, Prof. Luiggi has given an account of steps that are being taken to use this steam on a large scale. Prince Ginori-Conti, to whom the earlier experiments were due, acting on the advice of the Tosi Works, of Legano—specialists in steam turbines and alternating electric generators—ordered three groups of condensing turbo-electric engines, each of 3,000 k.w., working with superheated steam at 1½ atmospheres, to be worked by the head of the volcanic steam jets. The steam is not used direct in the turbines, on account of the corrosive elements, which it contains, but fed to specially constructed multi-tubular boilers which, in turn, give off the steam used in the turbines. In the boiler the volcanic steam gives up about 60 deg. C. of its heat, the temperature falling from 180 to 120 deg. C. The steam generated in the boilers and used for the turbines is thus ordinary water steam, which, on its way to the turbine passes along aluminum pipes heated outside by a current of superheated natural steam, at 180 deg. C.

After passing through the turbine that steam is discharged into a surface condenser, the circulating water of which is in its turn cooled in an ordinary cooling tower. The condensed steam from the turbines is, of course, pumped back into the boilers and thus no natural steam ever comes in contact with the turbines; by this arrangement corrosion is completely avoided. Professor Luiggi states that one of the 3,000 k.w. units has been at work since January, 1916, the second since April, and the third has just been started.

So far, the first two groups have worked quite successfully, and have been a great boon to the industries of Tuscany, greatly crippled by the scarcity and high price of coal. The very successful harnessing of volcanic heat to an electric power house can be increased practically to hundreds of thousands of horse-power, as the region of the steam-jet extends for many square miles.

REFRIGERATING PLANTS FOR NEWFOUNDLAND

ARRANGEMENTS have been completed by a fish corporation for the erection of a number of cold-storage plants at various places on the coast of Newfoundland. The principal plant will be erected in the city of St. Johns and will occupy ground space of about 245 by 90 feet. The plan calls for a six-story building, but only three stories will be erected at present. The basement will be of concrete, and above this the walls will be constructed of local brick. The lower flat will countain the freezing apparatus, having a refrigerating capacity of 150 tons, where fresh fish will be frozen in about two-hours. The ammonia plant for making artificial ice for preserving bait and for use on cars and steamers will be on the same floor. The second and third stories will be used for storage purposes. The entire building will have a capacity of about 10,000,000 pounds of frozen fish and will be equipped with two large elevators capable of carrying 5,000 pounds each.

Ten plants of much smaller capacity will be erected at other points, the largest of which located at Port aux Basques, will be capable of handling 1,250,000 pounds of fish. The others will have an average capacity of about 500,000 pounds. It is stated that the products of these smaller plants will be shipped over the railway to the plant at St. Johns, whence they will be forwarded to the English market. It is understood that contracts have been made with British firms to take all the frozen codfish that can be supplied for the next four years. The corporation is capitalized at $2,000,000 and expects to have its establishment working at full capacity within three years.

SMOKE PREVENTION

THERE has been considerable agitation great boom to the industries of Tuscany, portant cities smoke-prevention departments have been formed and laws made against smoke emission. The objections to smoke, as stated, are "public nuisance" and "fuel loss." The methods employed by smoke departments are effective in preventing the first, but the value of some of them as to the second is very doubtful. It is well known that the chief loss in a boiler plant is due to excess air (low CO_2), and not due to incomplete combustion, of which the result might be smoke.

To prevent smoke effectively, it is necessary to centre attention on the quantity of air used to burn the coal and keeping it down to a minimum, proper furnace temperature and possibilities for well mixing the combustible gases and the air. At present (with exceptions), most attention is paid to smoke and smoke alone, without paying the attention to excess air loss that it deserves. As a result many plants are wasting more fuel since operating smokelessly than before, because of using more excess air.

Smoke-prevention departments could greatly aid in preventing national fuel waste and some of them are doing so, but where they are not it can be laid to:—

(a) Political influence and interference.

(b) Lack of funds to employ expert inspectors.

(c) Employment of methods having no scientific basis and lack of effort to educate the engineer and firemen, while at the same time more force is employed than is good for the cause.

(d) Lack of confidence on the part of the power plant owner because of all of the above.

Exceedingly few firemen, not even 3 per cent., know the simplest rudiments of combustion. Many who are considered good firemen persist in operating their furnaces so that at least 20 per cent. of the fuel is wasted; at the same time claiming that it is the better and proper way. To overcome such conditions they must be educated.

It would be a great help if more of the simplest literature could be obtained, describing the economical process of firing, and this written in an interesting way. It is not meant that there is no such literature, for an immense amount of good has been done by different journals of this character, but the man who needs it most does not get it, and it would pay to bring it to him.

The U. S. Bureau of Mines would increase its usefulness by including in its excellent editions on fuel technology from time to time, bulletins of a thoroughly practical nature especially adapted to the average boiler-room man. These bulletins should be written by men who know the fireman and who have been through the mill themselves. After such bulletins are ready they should not be kept until those who need them write for them, but they should be given a forced circulation with the aid of boiler-insurance companies, smoke-inspection departments, business men's leagues, etc.

Power Transmission Section

LEATHER BELTING

A PECULIAR condition exists in the machine and railroad shops of the country in the purchase and use of their leather belting, and it may fairly be assumed that the majority of them are buying and using leather belting of a very inferior character, says L. W. Arny in the *Iron Age*. In some cases this is due to a deliberate selection of cheaper grades, but in most of them it is due to the ignorance of the purchasing authorities, the attraction of lower prices, and the delusion that quality can be secured without paying an adequate price for it. One of our important railroads has said in substance that they find certain second and third qualities quite sufficient for their requirements.

The practice in leather belting in most of these shops is based, at least in part, on the study on this subject originally formulated by Frederick W. Taylor, and by his coadjutor and successor, Carl G. Barth, and these men after considerable belting experimentation determined upon a tension equivalent to about 70 lb. per sq. in. as that giving most satisfactory results. It was understood that this tension was much below the actual capacity of the belts, but the purpose was to adopt a tension that would be such as to reduce to a minimum the labor and attention of maintaining it, and of securing a long life for the belt, and it was intended that by the use of leather belts of high grades, the utmost economy would be attained; this was doubtless the result, and Mr. Barth to-day after a good many years of experience with this tension, is still insistent that good qualities of belting only be used.

Working Tension Too Low to Measure Quality

But the use of this low tension, though conducing to the economy of operation and the long life of the belt, is so low as to make possible, with temporarily successful results, the use of much inferior qualities of leather belting, and these lower grades, introduced into the shops either intentionally, as with the railroad mentioned, or ignorantly through a bad purchase, have been sufficient to keep the pulleys in a state of revolution for a time, and their subsequent performance has been over-looked or forgotten. This is more particularly true where there exists so large a gap between the purchasing and operating departments as is usual with the railroads. Unless the leather belts supplied fail to do their work, the operating department is not inclined to make trouble with the purchasing department, shutting their eyes to length of life.

The idea that the cheaper grades of leather belting can produce the same economical results as the better qualities is just as fallacious as the same thought in application to other materials. A good leather belt is capable of such a long life under reasonable conditions, and real economy is so dependent upon length of life, that the use of inferior qualities made from belly and shoulder portions of the hide is pure extravagance, and yet many of our best shops are filled with the worst junk that the leather beltmaker can put together.

No Accepted Test For Belting

Leather belting does not lend itself to the mental processes of the average purchasing agent. It is a specialty which is poorly understood even by those most practical in its use. It is not standardized as are some other products. It cannot be bought as a standardized article on price only, and when the purchasing agent places his order or his contract with the lowest bidder, he gets only and not a particle more quality than he pays for. The lowest bidder is always the one least qualified to supply the goods desired. The fact that the receivers and the operating department are not qualified to determine the quality of the goods delivered from their appearance or from any tests which they are capable of applying is an open invitation or possibly a defiance to the lowest bidder to come in and defraud them. There will come a time when this condition will be changed, for the leather belting manufacturers through the Leather Belting Exchange, in connection with the Mellon Institute of Industrial Research, is at work in an effort to produce specifications that will really specify, and the results of which may be identified on delivery. At this time this is impossible, and the present variety of specifications for leather belting is ridiculous because no man can tell on delivery whether the goods comply with them or not.

There is a large opportunity for the machine and railroad shops of the country to make material savings in their belting expense by the use of better qualities. It is possible for them to secure a better efficiency from those belts in operation; to reduce the costs of care and maintenance, and to reduce the costs of replacement. Leather is a practically indestructible material. It does not corrode, oxidize, ferment or crystallize and time produces no effect upon it. There are records of belts which have carried their loads for 30, 40 and even 50 years and are still running, after having traveled millions of miles, and this wonderful efficiency should be secured for the machine and railroad shops. But it must be understood that the maximum efficiency and length of life can be secured only from use of the first quality, and not from the second and third quality belts bought because their first cost is smaller.

There need be little trouble about securing a good quality of leather belting for use in these shops if the purchasing departments will go about it properly. As previously explained, it cannot be bought on specification or price, but there are many reputable manufacturers whose brands and trademarks can be depended upon and a reliance upon recognized brands, and the payment of a sufficient amount of money, will secure the desired qualities. Mr. Arny is secretary of the Leather Belting Exchange, Philadelphia, Pa.

POSITIVE AND FRICTION CLUTCHES

By T. J.

THE attempt to find a satisfactory form of clutch has yielded many excellent types and designs, but no clutch yet invented has shown such all-round superiority as to supersede all other designs. The claw coupling is the simplest and most effective of all clutches when once it is in action, for it consumes practically no power, and shows no wear, but it cannot be put in and out of a gear except at slow speeds, or when the machine is stopped. For a drive that can be connected or disconnected at full speed and under full load, some form of friction clutch is necessary. The cone clutch is the simplest of all friction clutches, and although innumerable other types of friction clutch have been introduced—segment clutches, band clutches, disc clutches, magnetic clutches, centrifugal clutches, etc.,—it still remains a prime favourite. The conditions to be fulfilled by the ideal clutch are many and diverse. It must be simple in construction, and free from undue wear; it must engage smoothly, and when engaged must grip firmly, yet there must be no "bite" that will prevent easy disengagement; the grip must not be incurred at the cost of heavy pressure on the moving part, as there will be a wear

and loss of power; the amount of movement required to put the clutch into action must not be too great, and yet the clearance when out of action must be such as to ensure that there is no rubbing. These are but a few of the conditions to be observed.

Theoretically the ideal clutch, as suggested by Mr. W. G. Gass, would be a combination of friction and positive clutch. It would employ a friction arrangement for starting up, and when that had done its part a positive drive would come into operation, and take all the work of driving off the friction surfaces. The designing of a combination clutch of this kind is not an easy matter. The difficulty would come in providing for its being thrown out of gear with the same ease as a friction clutch, for when the positive part of the clutch comes into action it is this part which will be doing the work, and will be under pressure, and to withdraw this part from engagement will present the same difficulty as is found with a claw coupling.

BALL BEARINGS IN THE WOODWORKING INDUSTRY

TEN years ago ball bearing woodworking machines were a luxury. Very few were in use, because they were not needed, but labor cost began to climb and with it the construction of woodworking machinery underwent a complete change. Manufacturers demanded more work; production had to be increased to offset high expenses. This meant that each machine had to work at higher speed, and with heavier cuts. Immediately there was trouble. Bronze bearings which had been satisfactory, showed unexpected weaknesses. Hot boxes, burn-outs, and rapid wear were the rule. Evidently it was necessary to find some type of bearing which would stand up under heavy duty. After considerable experimenting some manufacturers turned to ball bearings, and their doing so marked the advent of ball bearings in woodworking machinery. From the very start they proved their ability to stand up to the most exacting requirements. Aside from this, however, ball bearings brought a host of advantages, among which were better work, more work, less power, less oil, cleanliness, freedom from hot boxes, reduced fire risks and lasting accuracy.

The advantages of ball bearings for woodworking machinery are: increased production; improved quality; accuracy of bearing detail; reduced maintenance; reduced number of accidents; bearing troubles minimized. A brief consideration of these points will prove each advantage clearly.

Reliability at High Speeds

It is plain that ball bearings would not be used if they were unreliable at high speeds, because makers and users demand speed. Ball bearings were tried when bronze bearings failed. After ten years of real service they are in use in most types of woodworking machinery, and this is the proof of their reliability at high speeds.

Increased Production

A knife rotating 8,000 r. p. m. makes many more cuts a minute than a knife rotating 5,000 r. p. m. This is one reason why ball bearings increase production—they allow higher speeds and more cuts per minute. It has also been found by practical experience that ball bearings give a great reserve power to the machine by reducing the power wasted in friction, therefore, machines equipped with ball bearings can take heavier cuts. This is particularly noticeable in such machines as planers and shapers. A ball bearing shaper will easily take cuts that are heavy enough to stall a bronze bearing shaper

Improved Quality of Work

Users soon found that the quality of work done on ball bearing equipped machines was better and more uniform than that done on plain bearing machines. There are reasons for this. First, ball bearings are extremely accurate; a wheel, a cutter cylinder, or an arbor mounted in ball bearings can be adjusted with a high degree of accuracy. Second, ball bearings are self-aligning; any bending of the shaft is taken up by them. The bearing itself is so constructed that, without any special housing, it will compensate for shafting that is out of line. It is also practically impossible to bind a ball bearing; the shaft runs freely in any position. It is well to remember this, because no matter how much care is taken, sudden loads and uneven pulls will cause bending and deflection of shafts. High speed also improves quality because high speed means more cuts per minute, resulting in cleaner cut work.

Bearing Detail Accuracy

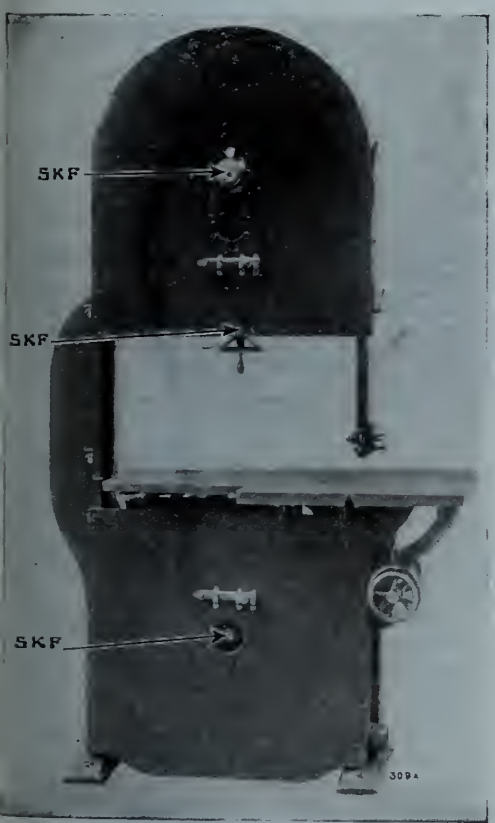
Ball bearings are made of high-grade materials, heat-treated in the most modern way and ground accurately to the ten thousandth part of an inch. The accuracy is lasting. Hardened steel balls rolling on hardened steel races practical-

BALL BEARING BARKER.

ly eliminate all wear. Ball bearings put in woodworking machinery in 1907 are running today and are still giving the same care-free, reliable service, as when new.

Reduced Maintenance

Due to their low friction, ball bearings are very economical to use. The power saved can be turned to other work and the saving made will show up in actual



BALL BEARING BAND SAW.

money. Ball bearings save oil. They use very little, only a small fraction of the oil used by plain bearings, the bearing being so housed that it will hold enough oil to last for months. Furthermore, the housing is oil-tight, so no lubricant can be lost by leakage. An oil tight housing also means a clean machine, a clean plant, protection from fire risk due to oil soaked waste and "live" belts unspoiled by oil.

Belts on ball bearing equipped machines last much longer, because they do not run high tension, and are free from oil. Also, the machines start easily, the bearings do not stick, and there is no excessive tension when starting. All of the above help materially to lengthen the life of belts. If motors are equipped with ball bearings, another big saving is effected. The motors use little lubricant and are largely free from many troubles that often tie up production. Ball bearings are practically wearproof, so there is no need of replacing worn bushings. The danger of worn bearings allowing the armature to touch the pole pieces is in consequence entirely avoided.

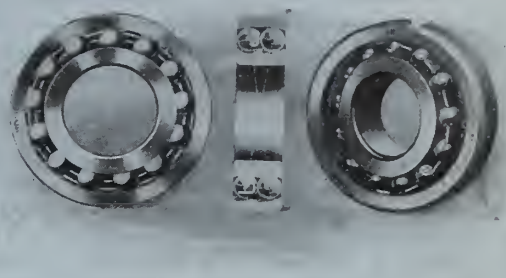
Reduced Number of Accidents

Poorly adjusted bearings, play, hot boxes, pools of oil—all are frequent causes of accidents or fire, and all are eliminated by ball bearing installation. The parts are carried in correct adjustment and the bearings themselves are non-adjustable; no adjustment is necessary. Play is the result of wear. Hot boxes may be said to be unknown where ball bearings are used. The bearing is constantly bathed by oil, and since there is no friction there is also no heat. Fires from this source are therefore effectually prevented. Another source of fire is oil-soaked waste. Sawdust or shavings soaked with oil have been the start of many fires. By using ball bearings, housed perfectly oil-tight, this danger is removed. Pools of oil that collect dirt and leave slippery spots are a constant source of danger.

Some of the advantages mentioned here are more important than others, also some of them are more marked in one type of machine than another; but no matter what the machine is, the service and advantages gained by equipping it with ball bearings are certain and great. A prominent manufacturer of woodworking machinery who is a large user of ball bearings has expressed his opinion very clearly in one of his folders, thus:—"Steel ball bearings have so many advantages over both bronze and babbitt bearings then the manufacturer who once uses them will be satisfied with nothing else, provided of course that the ball bearings in the particular machine he is using are of the highest grade and of the best type procurable." We are indebted to the SKF Ball Bearing Co. for the illustrations accompanying this article.

COKE FUEL FOR POWER STATIONS

THE Highways Committee of the London County Council has placed an order for eight coke-burning mechanical stokers for use under steam boilers at the Greenwich generating station. The use of mechanical stokers for firing boilers with coke fuel has passed the experimental stage in more than one power station, but the London County Council will no doubt regard the present installation as more or less experimental so far as they are concerned. It is calculated that the



RADIAL BEARING SHOWN IN NORMAL. SECTIONAL. AND IN DEFLECTED POSITION.

first set of stokers now contemplated will, if worked to their full capacity, consume 100 tons of coke per 24 hours; and having regard to the relatively high cost of coal, as well as the relatively greater degree of efficiency attained in burning coke, every effort will no doubt be made to use the new stokers to their full capacity. The present total coal consumption at the power station has been estimated at 165,000 tons per annum, and according to a figure recently published, the present price is approximately $8 per ton. Having in mind the huge surplus of coke available in London before the war, the financial advantages to the Council will be considerable.

From a national point of view, the advantages accruing from the policy of using coke in lieu of raw coal to the extent indicated are no less important and far-reaching in their incidence, in view of the abnormal and increasing cost of imported raw materials used in the manufacture of carburetted water gas, a commodity which however desirable and useful in normal times is now regarded as expensive from more than one point of view. Based upon the total yearly consumption which is by no means the largest of any individual power station in London, the valuable residuals which

MOUNTING OF A SHAFT IN BALL BEARINGS.

would be recovered by diverting this quantity of coal through the gas works would include 1,650 tons of sulphate of ammonia, 300 tons of high explosive material, and 1,650,000 gallons of coal tar.

High Pressure Air Compressor Design and Application*

By Joseph M. Ford

Compressed air at high pressure is beco ming an increasingly important medium in modern engineering practice and in naval warfare. The accompanying paper deals with the machines which produce high pressure air, leaving on one side the question of power transmission by compressed air. In passing, the principal advantages of this system are referred to, and will be seen to be of considerable value. They consist of the facility with which energy can be stored; the unlimited rate at which accumulated energy may be converted into useful work; and, apart from loss of efficiency, leakage cannot cause any awkward consequences.

ONE of the best instances of the adoption of high-pressure air as a medium for power storage is to be found in torpedo work. The torpedo is launched from the tube by means of compressed air, usually stored at a high pressure, and when in the water is propelled by an engine de-

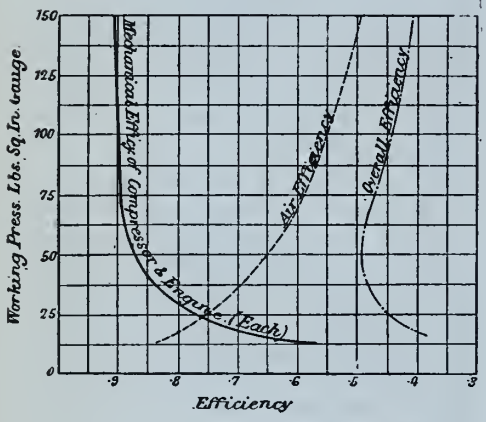


FIG. 1. SINGLE STAGE COMPRESSED AIR POWER TRANSMISSION. NO PREHEATING. MECHANICAL EFFICIENCY OF ENGINE ASSUMED TO BE SAME AS THAT OF COMPRESSOR. COMPRESSION IN LATTER AND EXPANSION IN ENGINE ASSUMED TO BE ADIABATIC.

riving most of its power from compressed air.

The starting of prime movers of the internal combustion type of considerable size is almost invariably carried out by compressed air, except perhaps in very special cases, such as some generating sets, where the dynamo can be "motored."

In marine work, with engines of the Diesel and other types, reversing and manoeuvring involve the displacement of a considerable amount of the valve-driving mechanism—most conveniently accomplished by compressed air.

One of the principal applications, however, is in the Diesel engine itself, where compressed air is used, not as a medium for energy storage in the usually accepted sense of the term, but to inject the liquid fuel into the working cylinders against the compression pressure of about 30 atmospheres (430 lbs. per sq. inch.)

In some oil-engined ships, high-pressure air is used for driving some auxiliaries, such as steering gear, main engine turning gear, small pumps, etc.. and in submarines the air is used, among other things, for blowing the ballast tanks.

*Part I. of a paper read before the Greenock (Scotland) Association of Shipbuilders and Engineers.

Pressures Adopted in Practice

Within limits, the lower the working pressure of the air, the higher the efficiency, but exigencies of space and weight may demand that the storage reservoirs shall occupy minimum space, in which case, for a given amount of energy stored, the pressure should be as high as possible—particularly, for instance, in a torpedo, where the dimensions and weight of power plant must be cut down to a minimum, almost irrespective of cost, and the pressures employed range accordingly from 2,000 to 4,000 lbs. per square inch.

With internal combustion engines, the design and type determine the pressure of the starting air. For example, gas, paraffin and petrol engines are frequently started with air at 100 to 300 lbs. per square inch. With Diesel engines of the four-cycle type about 300 lbs. per square inch usually suffices, whereas in engines of the two-stroke type the pressure may be as high as 1,000 lbs. per square inch. One of the disadvantages of using high pressures in this connection is that when starting a refractory engine—which does not readily pick up on fuel—the continued expansion of high pressure air in the working cylinders lowers the temperature to such an extent that the heat of compression is insufficient to ignite the injected oil. With reversing mechanism the obvious advantage accruing from the use of air at high pressures is that the dimensions of the servo-motors may be kept within small limits, which is of moment in some installations, although the higher the pressure the more difficult it is to maintain tightness and the better must be the fits, etc.

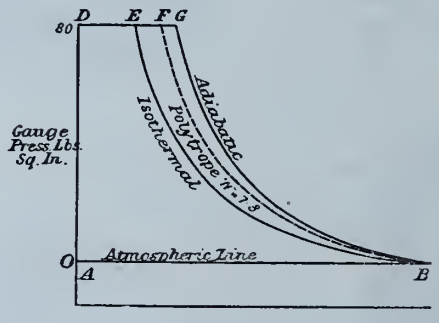

FIG. 2.

Initial temperature of air.. 60 deg. F.
Initial pressure ..... 14.7 lb. per sq. in. abs.
Final pressure ..... 94.7 " " "

WORK REQUIRED TO COMPRESS AND DELIVER 1 CUB. FT. OF FREE AIR.

Heat equivalent of work required for isothermal compression = area WYXZ.
Heat equivalent of extra work required if compression is adiabatic = area VWX (vertical shading).
Heat equivalent of extra work required if compression is polytropic = area TWX (diagonal shading).
Heat equivalent of work saved by cooling shaded horizontally.

For fuel injection. the air pressure is determined by the theoretical cycle of operations in the working cylinder, and varies from 600 to 900, and in extreme cases even to 1,000 lbs. per square inch, according to the particular design of engine. kind of fuel and load.

The question of driving auxiliaries by compressed air is a vexed one. Unless the air can be heated before expansion in the engine cylinder, low initial pressures should be used. With high pressures the re-expansion lowers the air temperature so much. due to work being done by the air. that snow forms and interferes with the working of the valves.

throttle passages, etc. Fig. 1 shows the theoretical efficiency of a transmission system when there is no pre-heating. The mechanical efficiency of the engine at the different pressures is assumed to be the same as that of the compressor at the corresponding pressures. The "air efficiency" is the ratio of work obtained from the air in the engine to the work done on the air in the compressor. A considerable gain in efficiency may be effected if the air can be heated before use, especially when this can be inexpensively done—e.g., by the exhaust gases of an internal combustion engine. The advantages of this system are nullified, more or less according to particular circumstances, by the low efficiency. Practical considerations, such as the question of leaks, etc., favor low pressures, whereas such considerations as the size of pipes, cylinders and storage generally demand a compromise, although it is cheaper to make an efficient large low-pressure reservoir than a satisfactory small high-pressure one.

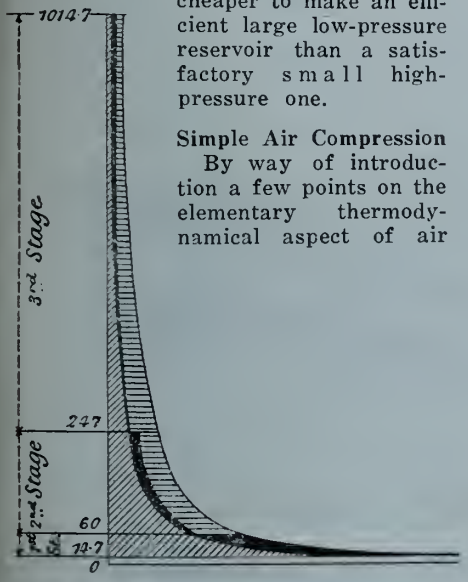

FIG. 4. Pv. DIAGRAM.

Simple Air Compression

By way of introduction a few points on the elementary thermodynamical aspect of air compression may assist towards the understanding of the special features of high-pressure compressors. If air be compressed isothermally, a certain amount of work has to be done—see Fig. 2, giving a theoretical indicator diagram for a machine delivering air at 80 lbs. per square inch. With isothermal compression the work required is represented by the area ABED. If the compression be adiabatic, then the additional work required is represented by the area BGE, from which it will be seen that the aim should be to secure isothermal compression, that is, to prevent increase of the temperature of the air during compression. Not only from the point of view of power absorbed should the temperature rise be small, but also for mechanical reasons, as later explained.

The index "n" in the standard equation $PV^n = C$ is in some ways a measure of the amount of heat abstracted during compression. With adiabatic compression its value for diatomic gases such as air is 1.41, and with isothermal compression its value is unity. In actual practice the amount of heat removed by a water-jacket on an air compressor cylinder is such that its value lies between about 1.28 and 1.35, the latter value being more applicable to large high-speed machines.

The line BF on Fig. 2 represents compression according to the law.

$$PV^{1.3} = \text{constant.}$$

This means that the saving in work effected by cooling the air during compression is represented by the area BGF. Moreover, the reduction in the final delivery temperature is to be noted.

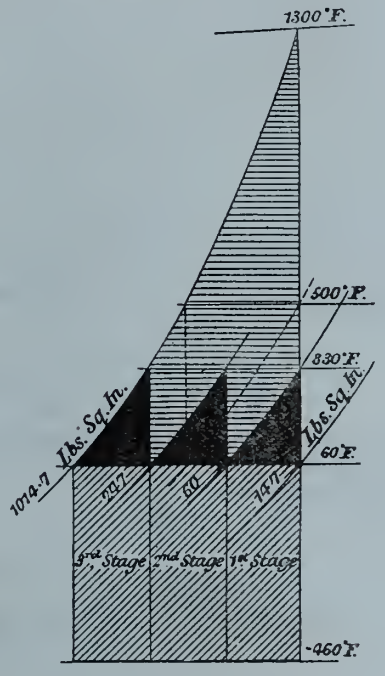

FIG. 5. Oo DIAGRAM.

THEORETICAL DIAGRAMS SHOWING SAVING EFFECTED BY STAGE COMPRESSION. COMPRESSION TO 1,000 LBS. PER SQUARE INCH GAUGE.

In an ideal compressor, i.e., one in which compression is isothermal, the work required per unit of air is represented by the diagonally shaded area of each diagram. If compression were carried out in one stage the work required is represented by the total area of the diagram. The horizontally shaded area represents the work saved by compressing in three stages and intercooling. The darkly shaded area represents the amount by which the work required for three-stage compression is still in excess of the ideal. Note the huge saving of three-stage over one-stage compression. In this case the saving is 29½ per cent.

The diagram in Fig. 3 is the "theta" "phi" diagram corresponding to Fig. 2. This shows rather more clearly the difference in the work required and temperature attained by compressing under the various conditions. The figure is self-explanatory.

Compression in Stages

When pressures of 1,000 lbs. per square inch and over are required, the temperatures attained by single-stage compression would be extremely high. If lubricating oil could be eliminated from the problem, careful design might succeed in producing a compressor that would stand the stresses set up by the high temperatures.

Lubricating oil burns in air at such temperatures, with the result that the pistons would become carbonized, the valves clogged and the pipes sooted-up. In addition, high temperatures have deleterious effects on tempered steel valves and springs. With large high-speed machines the temperature, coupled with the peculiar fatigue phenomenon, makes it well nigh impossible to get satisfactory working with temperatures higher than those consequent upon about six compressions in one stage.

If the excessive work of compression and high temperatures are to be avoided, the heat must be abstracted from the air in the period between the start of compression and the commencement of delivery. Jacketing alone is insufficient. The method that suggests itself is to compress the air a small amount, then withdraw it from the cylinder, cool it to atmospheric temperature, and return it to the cylinder. Next, move the piston further to compress the air still more, and repeat the cooling process, and so on, until the required pressure is attained. This is virtually the method adopted in practice, except that in lieu of carrying out the whole process in a single cylinder, one cylinder is devoted to each stage of compression, and between each stage the air is passed through an intercooler to reduce its temperature to the initial atmospheric temperature. The saving in work effected by stage compression with intercooling is shown in Figs. 4 and 5. The PV diagram, Fig. 4, has been drawn for a three-stage machine compressing to 1,000 lbs. per sq. inch.

If the heat of compression could be removed as fast as it is generated, as with isothermal compression, the work required to compress unit volume would be represented by the diagonally-shaded area. This is the ideal condition. If the compression were carried out in one stage and no heat were removed—that is, if the compression were adiabatic — then the work required to compress unit volume of air would be represented by the total area of the diagram, that is, the diagonally, plus the black, plus the horizontally shaded part. The ratio of this total work to that required in isothermal compression will be noted. If, again, the air were compressed adiabatically to 60 lbs. per square inch only and then cooled to its initial temperature, its condition will then be the same as it would have been had it been compressed isothermally. From this point the second stage of compression is carried out and the cooling process repeated, meaning that the area of the second stage diagram is only the diagonally shaded portion plus the black portion, the horizontally shaded part being completely saved, due to the reduction in the volume of air dealt with, as a result of the intercooling.

Similar conditions obtain in the third stage, the horizontally shaded part again representing work saved. The work required for adiabatic compression in three stages is thus represented by the diagonally shaded portion plus the black portion, which latter represents the amount by which the work required is still in excess of the ideal.

Fig. 5 is the "theta" "phi" diagram corresponding to the PV diagram in Fig. 4.

The corresponding areas are similarly shaded. In addition to the work required, this diagram shows the temperatures attained in compression under the various conditions. The reduction of the temperature due to staging is clearly shown. The 1,300 deg. F. is a theoretical value, 500 deg. F. is the temperature which would be attained were the compression carried out in two stages, and 330 deg. F. is the result of three-stage compression. In the case under consideration the total work is equally divided between the stages, whereas in actual practice this condition does not generally hold exactly.

The temperatures attained in the cylinder when air is compressed to various pressures in one, two or three stages, with intercooling, are given in Fig. 6. Piston friction and the effect of the cylinder walls have been neglected. As previously stated, the high temperatures could not be dealt with in practice. The temperatures given for two and three-stage compression are based on the assumption of perfect intercooling, which

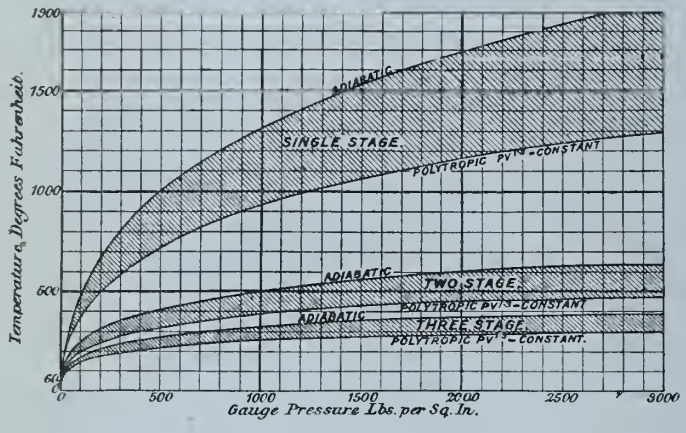

FIG. 6. TEMPERATURES ATTAINED WITH ONE, TWO AND THREE-STAGE COMPRESSION TO VARIOUS PRESSURES. INITIAL TEMPERATURE IN EACH STAGE OF COMPRESSION ASSUMED TO BE 60° FAH.

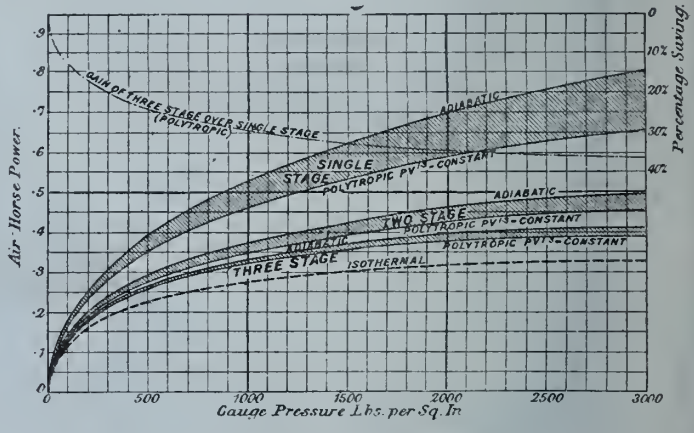

FIG. 7. AIR HORSE-POWER REQUIRED PER CUBIC FOOT FREE AIR PER MINUTE WITH ONE, TWO AND THREE-STAGE COMPRESSION TO VARIOUS PRESSURES.

condition holds for well-designed machines. In some plants where there is a copious supply of cold water, and where intercoolers of liberal dimensions are fitted, the air can be cooled between the stages to less indeed than the initial temperature.

Fig. 7 gives the air horse-power required to compress 1 cub. ft. of free air per minute in one, two and three stages to various pressures, and shows how the power required approaches the ideal (isothermal compression), and the ill-effects of inefficient jacketing diminish as the number of stages is increased. For example, with air compressed to 1,000 lb. per square inch in one stage, according to the law $PV^{1.3} = \text{constant}$, the power required would be 0.46 a.h.p. per cubic foot; but if the cooling were very inefficient, so that the compression were adiabatic, the power would rise to 0.53 a.h.p. per cubic foot—an increase of 15 per cent. With three-stage compression, according to the same law, the power required would be 0.32 a.h.p. per cubic foot, and in this latter case, assuming that the cooling were inefficient, the power would only rise at the most to 0.335 a.h.p. per cubic foot—an increase of 5 per cent., against the 15 per cent. obtained when compression is carried out in a single stage.

Apart from the questions of efficiency and temperatures, an advantage of staging is the reduction of crankpin loads and stresses generally—the reasoning being exactly the same in this connection as for a compound or triple-expansion steam engine. Theoretically an infinite number of stages is required, but practical considerations, such as the multiplicity of parts, the low mechanical efficiency, weight, cost, etc., limits the number of stages.

Pressures and Number of Stages

The best practice is as follows: The maximum terminal pressures are, for one stage, 80 to 100 lb. per square inch; two stages, 600 lb. per square inch; three stages, 1,500 lb. per square inch; four stages, 2,500 to 3,000 lb. per square inch; five stages, 4,500 lb. per square inch; and above 4,500 lb. per square inch, six or seven stages to 6,000 lb. per square inch, which is about the highest pressure for which an air compressor has been constructed.

In the case of very small machines these pressures, for a given number of stages are often exceeded in order to reduce complication. For example, machines have been constructed and work quite satisfactorily when compressing to 2,500 lb. per square inch in two stages. The temperatures attained, however, make it necessary to carry out the cylinder lubrication by soapy water.

Effects of Cylinder Clearance Volumes

An important consideration in the design of a multi-stage compressor is the computation of the clearance volumes of the various cylinders. By clearance volume is understood not merely the volume of the space which separates the piston from the end of the cylinder when the crank is on dead centre, but, in addition to this, the volume of all valve ports and pockets, space behind piston rings if these are air-packed, and, in short, any space into which the air can be compressed, without passing through the delivery valve. With an ordinary single-stage compressor, such as would be used to drive pneumatic tools in a shipyard, the designer aims to reduce the cylinder clearance to the minimum, for by so doing a greater quantity of air is delivered per stroke than would be the case with a larger clearance. Fig. 8, which is a theoretical card for a cylinder compressing to 80 lb. per square inch, is given in explanation. With zero cylinder clearance the volume of air delivered is represented by CD, whereas with 10 per cent. clearance and the same cylinder dimensions the volume delivered becomes FD. Less air is drawn into the cylinder per stroke, since the air left in the clearance space re-expands along DE, for a portion of the suction stroke, as shown, and the suction valves do not open to admit a fresh supply of air until the point E in the stroke is reached. In this way the volume of air aspired is only EB, as compared with AB—the volume dealt with in the same cylinder without clearance. The ratio $\frac{EB}{AB}$ is known as the Indicated Volumetric Efficiency, and in this particular case is about 69 per cent. The smaller the clearance space, the nearer will E be to A, i.e., $\frac{EB}{AB}$ will be greater, and a larger volume of air will consequently be dealt with per stroke.

With a large clearance a larger cylinder is required to deliver a given amount of air than with a small clearance, yet the indicated work done per unit volume of air dealt with remains the same, although the larger cylinder makes for a heavier and more costly machine, with greater piston loads, so that in general practice the clearances are made as small as possible. Referring again to Fig. 8, the higher the compression is carried, the further will E be removed from A, that is, the higher the delivery pressure at which a given cylinder is working, the less will be the indicated volumetric efficiency. Further, if the clearance air receives heat from the cylinder and piston whilst expanding, the law of expansion will approach the isothermal and the pressure of the clearance air will take the longer to drop to the suction pressure.

or E will be still further removed from A to G.

It is to be emphasized that the air should not receive heat whilst re-expanding, or, in other words, the clearance space should be as efficiently cooled as possible. The cooler the walls of the

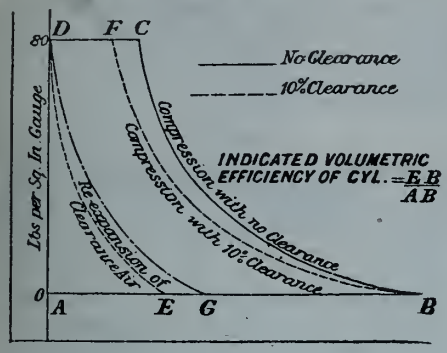

FIG. 8.

clearance space, the more rapidly will the pressure of the re-expanding air fall to the suction pressure and the greater

$$\frac{EB}{AB}$$

will the ratio become. Moreover, if the clearance air receives heat whilst re-expanding, its temperature at point E will be considerably higher than the temperature of the incoming air. As a result of the mixing of the new supply with the hot clearance air, the temperature at the end of the suction stroke, i.e., at B, will be higher than it would have been had there been no hot air left in the cylinder at point E, thus reducing the weight of air dealt with per stroke and increasing the temperature of compression. In any case the temperature of the air at B must be higher than that of the suction air, owing to contact with the hot walls and piston.

In modern practice, the cylinder clearance volume for a single-stage compressor or low-pressure cylinder of a multi-stage machine is seldom less than 3 to 4 per cent. of the volume swept out by the piston. It is usually found that, within limits for practical reasons, the larger the machine, the smaller the percentage clearance.

If a single-stage machine were constructed to compress to a moderately high pressure, say, 165 lb. per square inch, the indicated volumetric efficiency at the best would not be more than about 80 per cent., whilst the ratio of volume of free air delivered to volume swept by piston would be very much lower still, due to the addition of heat before compression commenced. Further, the cross-head loads would be very great, due to the final delivery pressure being exerted on the whole area of the large piston. The twisting moment diagram for the machine would be uneven, and, perhaps of most consequence, the final delivery temperature would be excessively high.

If, on the other hand, the same size of cylinder were used with a high-pressure cylinder added thereto, so that the first only compressed to 37 lb. per square inch, the indicated volumetric efficiency would be increased to about 94 per cent., due to the lower delivery pressure bringing the point of the low-pressure diagram corresponding to E in Fig. 8 nearer to A. With the high-pressure cylinder mounted in tandem with the low-pressure, it is possible that the weight of the machine per unit of air delivered would not be more than when the compression was carried out in one cylinder. Staging nullifies to a large extent the effects of clearance volume on the volumetric efficiency of a compressor, besides obviating the difficulties with loads and temperatures.

In both the French and German languages the expression for clearance volume, literally translated, means "injurious space," yet the effects of clearance in some cases are beneficial. In a cylinder with no clearance the whole load at the commencement of the stroke due to the acceleration of the moving part comes upon the crank-pin. With clearance, the re-expansion of the clearance air helps largely to accelerate the masses, and an interesting case in this connection may be cited.

With steam-driven compressors it is common practice to mount the steam cylinders in tandem with the air cylinders, in which case the setting of the steam valves must be so arranged that admission is late instead of early, as is usual. If the full steam pressure were applied to the piston before the clearance air pressure in the air cylinder had become reduced by re-expansion, unnecessarily high loads due to these simultaneous full pressures, less the inertia effects, would be imposed upon the connecting rods, etc. High speeds with increased inertia forces tend generally to reduce crank-pin loads. With steam-driven compressors of the foregoing type the greater the clearance volume of the air cylinder the later must the steam admission be timed.

Effects of Clearance in the Higher Stages of a Multi-Stage Compressor

In a multi-stage compressor the work done in the various stages may be varied within fairly wide limits merely by adjusting the clearance volumes of the various cylinders, excepting the low pressure. Suppose, for example, it is required to reduce the proportion of work done in the high-pressure stage of a three-stage compressor in which the high-pressure clearance volume is 10 per cent., and with stage pressures—low pressure 45 lb. per square inch, intermediate pressure 300 lb. per square inch—working against a final delivery pressure of 900 lb. per square inch.

The work done in compression varies as the ratio of final to initial pressure, so that any desired reduction in any given stage can only be effected by reducing this ratio, or in this case by increasing the high-pressure suction pressure, since the final delivery pressure is fixed. The compressor capacity being unaltered, an increase in the high-pressure suction pressure necessarily involves a corresponding reduction in actual volume of high-pressure suction. Since the volume swept by the high-pressure piston remains the same, it is clear that the only way to ensure a reduced suction volume is to decrease the volumetric efficiency of the high-pressure cylinder by increasing the clearance volume, with the result as shown in Fig. 9, where the high-pressure diagram with the original 10 per cent. clearance, together with the diagram resulting from an addition of 20 per cent. extra clearance, are given. The area of the diagram is considerably reduced, the high-pressure suction pressure (the intermediate-pressure delivery pressure) rises from 300 lb. per square inch to 375 lb. per square inch (gauge-pressure), this increase being necessary in order to get the whole of the air into the high-pressure cylinder. The effect on the low-pressure delivery pressure is slightly to increase it, due to the reduced volumetric efficiency of the intermediate pressure cylinder, resultant upon the expansion of the intermediate pressure clearance air from a higher pressure. The actual increase in low-pressure delivery pressure depends upon the intermediate pressure clearance volume. If the intermediate pressure cylinder had no clearance volume, which is impracticable, the low-pressure pressure would remain unaltered. The slight increase in low-pressure delivery pressure somewhat reduces the volumetric efficiency of the compressor.

The simple method of altering the distribution of work would be convenient where the high-pressure delivery temperature was found to be excessive (see later), or in cases where the turning moment was unsatisfactory. The clearance volume can be increased by the addition of a hollow pocket, but cannot so easily be reduced.

Some multi-stage compressors are required to work for long periods at varying delivery pressures, or, in the case of a charging compressor, at a constantly increasing pressure from atmospheric to the full bottle pressure. With Diesel engines it is usual to regulate the blast pressure by throttling the fuel-injection

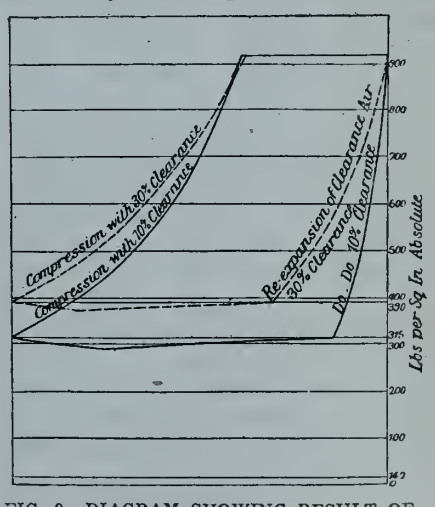

FIG. 9. DIAGRAM SHOWING RESULT OF INCREASING CLEARANCE VOLUME IN HIGH PRESSURE CYLINDER.

air compressor suction, so that instead of compressing and blowing the excess to waste, only the requisite amount is dealt with. The effect on the distribution of work, temperatures, etc., occasioned by

this throttling should be considered—especially with marine engines, where the compressor may run for long periods in this condition.

In all machines there are certain stage pressures which give the best all-round running, as regards temperatures, loads, balance, etc., for each delivery pressure. If these stage pressures are accurately determined for the normal final delivery pressure, then it is safe generally to assume that the particular stage division of work so obtained will also be the best proportion for any other delivery pressure at which the machine is likely to work. With Diesel engine fuel-injection compressors this state of affairs rarely obtains. In a three-stage compressor designed for 800 lb. per square inch working pressure, and run at, say, 900 lb. per square inch, the low-pressure and intermediate-pressure pressures will not increase in proportion to the final delivery pressure—actually in the majority of cases they alter little. By suitably proportioning the cylinder clearance volumes of the various stages the machine can be made automatically to divide the total work between the stages in a given proportion, no matter what the delivery pressure may be.

Figs. 10 and 11 show approximately the stage pressures which would be obtained in three machines of the same capacity when working at different pressures. Each machine is designed for a delivery pressure of 900 lb. per square inch, and at this pressure the stage pressures are: low-pressure, 45 lb. per square inch (gauge pressure). The heavy lines on the diagram show what the pressures should be to secure an approximately constant proportional division of work between the stages. The lines marked (a) show the pressures which would obtain in a compressor having cylinder clearances of: low-pressure, 4 per cent.; intermediate-pressure, 5 per cent.; high-pressure, 10 per cent.

The rise in the stage pressures as the final delivery pressure increases is seen to be comparatively small. The lines marked (b) show the pressures with a compressor of the same capacity when the cylinder clearances are: low-pressure, 4 per cent.; intermediate-pressure, 10 per cent.; high-pressure, 20 per cent. Here it is seen that the rise in stage pressure is much more marked than in the first case, that is to say, with these increased clearance volumes the proportional division of work between the stages is more nearly constant than with the smaller clearances. The lines marked (c) give the pressures which would obtain with a machine having clearances: low-pressure, 4 per cent.; intermediate-pressure, 15 per cent.; high-pressure, 30 per cent.

In this case the rise in stage pressures as the delivery pressure increases approximates much more nearly to the "ideal;" that is, the proportional division of work between the stages is very nearly constant, so that the balance of the machine is more likely to be maintained than in the first case, and, further, the final delivery temperature will be lower, for in the first case, when the machine is working at a pressure higher than its designed pressure of 900 lb. per sq. inch, the high-pressure stage is taking more than its designed share of the work. For example, if the first machine (case "a") were run at 1,200 lb. per square inch, the compression ratio in the high-pressure cylinder would be:—

$$\frac{1215}{335} = 3.63$$

If the last machine (case "c") were run at 1,200 lb. per square inch, the high-pressure compression ratio would be:—

$$\frac{1215}{370} = 3.28$$

This means that the temperature attained in the machine with the large clearance would be less than in the machine with the small clearance on account of the smaller compression ratio. Furthermore, if the large clearance is composed of a connecting pipe within a water-jacket, as is sometimes the case, the cooling during compression is improved, resulting in a decrease of the value of "n" in $PV^n = \text{constant}$, still further reducing the temperature. Again, the clearance space being so efficiently cooled results in an increase in the value of "n" for the re-expansion of the clearance air. The incoming air mixes with this comparatively cool air, and consequently the initial temperature is not unduly raised.

The main point, however, is that by correctly arranging the clearance volumes the machine can be made to divide the total work into the best proportions for any delivery pressure with which the compressor may have to deal. A minor point is that with increasing delivery pressures piston leakage becomes greater, and the volumetric efficiency at the higher pressures is less than at the lower. If the low-pressure pressure increases with the delivery pressure, the indicated volumetric efficiency of that cylinder is decreased in addition—or, in short, the overall volumetric efficiency of the machine with the big clearances is slightly less than that of the machine with the small clearances when the delivery pressure is higher than that for which the compressor is designed.

The difference, however, is not worth considering. (It may be mentioned that the lines in Fig. 10 should not actually be quite straight. They are sufficiently accurate, however, as in practice it is impossible to estimate the pressures to within a few pounds.)

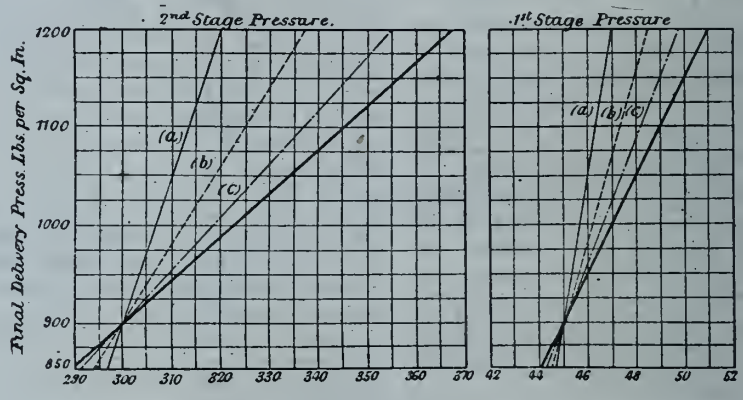

FIG. 10. FIG. 11.

DIAGRAM SHOWING APPROXIMATELY THE STAGE PRESSURES ATTAINED WHEN THE COMPRESSOR IS DELIVERING AGAINST DIFFERENT FINAL PRESSURES.

Each machine is designed for a final delivery pressure of 900 lbs. per square inch with L.P. and I.P. pressures of 45 lbs. per square inch and 300 lbs. per square inch respectively.

(a) For a compressor whose clearance volumes are: L.P., 4 per cent., I.P., 5 per cent., H.P., 10 per cent. of volume swept by piston.

(b) For a compressor whose clearance volumes are: L.P., 4 per cent., I.P., 10 per cent., H.P., 20 per cent. of volume swept by piston.

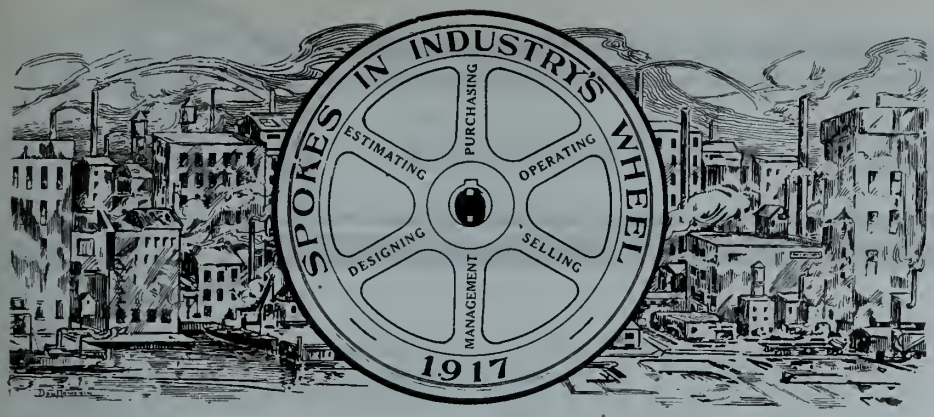
(c) For a compressor whose clearance volumes are: L.P., 4 per cent., I.P., 15 per cent., H.P., 30 per cent. of volumes swept by piston.

The heavy line shows what the pressures should be if the division of work between the stages is to remain in the same proportion for all delivery pressures.

THREE-CYLINDER COMPOUND ELECTRICAL UNIT

THE new 60,000 kilowatt unit to be installed in the 74th Street station of the Interborough Rapid Transit Co., New York, where three 30,000 kw. cross compound Westinghouse turbine generators have been in successful operation for over two years, will consist of a high pressure and two low pressure turbines, each coupled to a generator. Each of the three turbo generators making up the unit is to have a governor so arranged that if for any reason the circuit should open on the high pressure turbo generator, steam will be shut off from that particular one, and the two low pressure turbo generators will operate under governor control with high pressure steam. Likewise, should anything happen to both the high pressure and one of the low pressure turbo generators, or to the two low pressure turbo generators, the remaining one will operate and carry the load. The turbines which will operate at 220 lbs. absolute steam pressure, 120 degrees superheat, 20-inch vacuum, and the generators which will have a capacity of 60,000 kw. continuously, or 70,000 kw. for two hours, are being furnished by the Westinghouse Electric & Mfg. Co., of East Pittsburgh, Pa.

A person don't mo'n realize he's a descendant befo' he's a' ancestor.—Ruth McEnery Stuart.



The constitution of industrial enterprise is largely departmental—"Spokes in a Wheel." This series has for its object the featuring of, in racy, interesting and instructive fashion, the training, experience and achievement of those who to-day are transmitting effectively, energy in a variety capacity as "Spokes in the Wheels" of steam, electrical and hydraulic and refrigeration engineering.

JOHN WILKIE TAYLOR

THE increasing importance of the shipping industry, which is now being brought before the general public by events not of the pleasantest, is of more than passing interest to our readers, not only on account of the manufacturing activity which is expected to result from present developments, but also because of the more intimate knowledge ensuing with regard to ships' equipment and personnel. The part played by the machine shop in the annual round of marine life in this country is too important to be overlooked. Not only so, but the influence of early experience during the formative period of an engineer's life has more than a little to do with the ultimate niche which he may occupy in industry's gallery.

As chief engineer of the Western Canada Flour Mills Co., Goderich, Ont., John Wilkie Taylor occupies a post of considerable importance not only from a technical viewpoint, but also, at the present moment, from a standpoint of international exigency; a daily capacity of 10,000 barrels of flour by the various plants will perhaps facilitate perception of the reference. Despite the fact that he has a "shore job," Mr. Taylor's success has been largely influenced by a happy combination of constructive and operative experience. Born of Scottish parents at Nottawa, Ont., 1868. Mr. Taylor is Canadian to the core, his life activities having afforded opportunity for becoming intimately acquainted with many widely separated parts of his native land.

His early education was obtained in the public schools of Nottawasaga Township, passing the entrance examinations at 13 years of age. In May, 1880, an apprenticeship was commenced in the establishment of Nathan Veitch, ironfounder and machinist, at Nottawa, and although, as our "Spoke" remarks, the plant was somewhat primitive, the proprietor, by reason of his personal interest in the youthful employee, more than made up for the shortcomings of his equipment. Mr. Veitch was a real "old guard" of the trade, having come from the Howden shops in Glasgow, Scotland, and the thorough manner in which he grounded our friend in the rudiments of the foundry and mechanical trades has been the cause of life-long gratitude on the part of Mr. Taylor.

On the conclusion of his apprenticeship Mr. Taylor spent a year at Collingwood as assistant engineer in a large saw mill owned by the A. M. Dodge Co.,

JOHN WILKIE TAYLOR.

of New York. His contact with shipping at this port created a desire for marine experience, and during the three seasons ending 1890 he was in charge of small craft plying from that port. A position as staff engineer with the Great Northern Transit Co. of Collingwood was followed in 1894 by appointment to the post of chief engineer in charge of the fleet of the Dominion Fish Co., Georgian Bay. This position he relinquished for a year to join the Holland and Emery Lumber Co., at Byng Inlet, returning to the former company and superintending the overhauling of their fleet while wintering at Goderich. The year 1900 was rendered memorable in our "Spoke's" life by the burning of the passenger steamer Persia, of which he was chief engineer. The event was not without its recompense, as he had full charge of the rebuilding of the engines, boilers and mechanical equipment, a task which was of considerable value in view of the experience obtained, as was evidenced by the performance of similar work for the Dominion Fish Co., in connection with their passenger steamer Manitou.

Recent events have acted as a forcible reminder of the three years from 1904 to 1907, which were spent as chief engineer on the steel freighter Algonquin, this craft having recently fallen a victim to the torpedo of a Hun submarine off the coast of England. Mr. Taylor at this time was a strong advocate for the adoption of quadruple expansion engines, and while a bulk lake freighter of 10,000 tons was so fitted at that time and demonstrated the efficiency of the type of engine, further adoption was negatived by the extra amount of space required. His admiration for this highly developed type of engine was given full scope, when after four years with the Montreal Transportation Co., he became chief engineer of the turret steamer Scottish Hero, of the Canadian Lake & Ocean Navigation Co. This vessel had quadruple expansion engines, and had been refitted with Scotch boilers for 215 lbs. pressure, the two years' operation of which provided additional experience of a valuable nature, calculated to render our friend particularly fitted for the control and direction of the extensive equipment for which he is now responsible, and to which he was appointed in 1913, resigning from an important appointment with the Merchants' Mutual Line to accept the position.

The practical experience outlined has been combined with frequent opportunities to study power plant conditions in the States as well as Canada, and Mr. Taylor speaks highly of the degree to which Western Canada industrial equipment has been developed. A feature of Mr. Taylor's success has been the extent to which he relied on self-tuition for acquiring his theoretical knowledge. During early days in lake service, the winter months were spent in machine shops, and evenings devoted to study, the benefits being evidenced by the steady progress in his profession. His advice, therefore, to the young stationary engineer has the feature of personal success behind it. "I most strongly advise serving an apprenticeship in some good engineering shop along with a technical school training, and throughout life a diligent study of trade and engineering journals.

As is frequently the case with men

(Continued on page 148.)

Electricity and Hydraulics

BRUSHES FOR COMMUTATORS AND SLIP RINGS

THE nearly universal adoption of commutating poles, together with increasing commutator speeds and increasing brush densities, has made the problems of producing and selecting proper brushes for commutators and slip rings of importance of the first magnitude, says Charles H. Smith, Engineer, Executive Department, Westinghouse Electric & Mfg. Co., in The Electric Journal.

Brush Composition

Brushes are composed principally of: Carbon, carbon and graphite, graphite (natural), electro-graphite, metal and graphite (metal-graphite), carbon and wire gauze, copper leaf.

Carbon is a non-metallic element found in all organic substances, and for commercial purposes in anthracite and other coals and in charcoal. The amorphous or uncrystallized form includes charcoal. coke, lampblack, etc.

Graphite (natural), also known as black lead and plumbago, is a crystalline form of carbon. It is found in many forms and is widely distributed, Ceylon being perhaps the chief source of that used in commerce.

Electro-graphite (artificial graphite), is prepared commercially by heating coke (or other amorphous carbon) in an electric furnace and converting it from the non-graphitic to the graphitic state.

Combinations of carbon, carbon and graphite, graphite, and in some instances pulverized copper, are mixed with, or without, abrasives and binders, extruded or pressed into shapes varying from the size of the finished brush, to blocks and slabs of many forms and dimensions, which are baked or burned for use as brushes. The blocks and slabs are subsequently sawed and ground into sizes to suit the market demands. Brushes may be ground to almost any shape and can be furnished in block shape, bare or copper coated, drilled for, or fitted with, shunts, milled to the angle or radius to fit the commutator or rings, fitted with caps to protect the tops from the pressure springs and, if desired, equipped with almost any supplied or specified brush-lifting clips or devices.

The baking of the brush material is subject to many of the difficulties encountered in baking or firing earthenware. It is well known that a large piece of crockery or earthenware is more difficult to produce than a small piece, the reason being that there is more material and, consequently, more likelihood of warping, cracking, etc., from uneven burning or firing. The same troubles occur with brush material. It is obvious, therefore, that brushes made from small blocks, bricks, or slabs, or carbon, are more likely to prove uniformly good, or homogeneous, than brushes made from larger sizes of the same materials and mixings.

"Capping" and "Coating" Brushes

Soft brushes require protection from the wearing effect of the tension spring hammer. This protection consists of a metal cap which may cover the entire top of the brush, or merely that part upon which the spring presses. It frequently happens that the resistance between the brush and holder is less than that between the brush and shunt. As a consequence, the function of the shunt is usurped by the holder and the tension spring, resulting in the burning of the brush sides and in the destruction of the spring. This indicates that the cap should be integral with or attached to the shunt, or that the shunt attachment is defective. The definite way to preclude this too frequent possibility is to devise means to cause the shunt to perform the function of carrying the total, or substantially the total current handled by the brush. Fundamentally, such a means is in no sense an impossibility, and sooner or later will, no doubt, be put into practical form. The sooner, the better.

If the shunts perform their function properly there is no electrical reason for copper coating the brushes (unless it be immediately under the shunt, for the purpose of improving the contact between the shunt and brush), and less reason for the subsequent tinning of the copper. In case the brush is soft, or mechanically weak, it is desirable to protect it from mechanical shocks, and from wear due to rubbing against the sides of the holders and against the brush tension springs. For this purpose a copper or tinned copper coating is desirable.

Terms Used in Connection With Brushes

The following explanations of a few of the more important terms used in connection with brushes may prove instructive:—

Contact Drop refers to the drop between the brush and the commutator. The contact drop differs with different materials, different brush pressures and different loads. For a given material and given load the contact drop decreases with increased pressure and increases with the load. It varies but little with changes in speed above 2,500 feet per minute, and but little with temperature changes under normal conditions. Presupposing that the brush and spring pressures are identical, the contact drop between the commutator and positive brush differs from that between the negative brush and commutator on any given machine.

Brush Friction.—The coefficient of friction depends upon the brush material, brush angle and commutator speed. With a given material and brush angle, the coefficient of friction increases with load and brush pressure and, generally speaking, decreases with increased commutator speed. Increased temperatures, in actual practice, justify the conclusion that the friction coefficient increases with increased temperatures.

Specific Resistance.—The ohmic resistance of a cube having one-inch sides.

The Current Density (or carrying capacity) of a brush is based on its maximum continuous current capacity per square inch, without glowing, honeycombing, undue heating, or sparking.

Glowing.—A brush is said to "glow" when it becomes red or incandescent in spots in proximity with the commutator. This is due to the short circuiting current under the brush or to the short circuiting current in combination with the working or kilowatt current. It may also be due to a lack of homogeneity of the brush (hard or soft spots of the same or different materials having characteristics foreign to the material in the body of the brush); to incorrect brush position; to improper brush selection; to selective commutation; to the brush covering too many bars; to high mica; to the machine having inherently poor commutating characteristics due to improperly shaped or spaced main poles or commutating poles; to bad commutating pole adjustments, or to a poor distribution of armature windings. In event the glowing cannot be stopped by

JOHN WILKIE TAYLOR

(Continued from page 147.)

much occupied in industrial pursuits, Mr. Taylor has not spent much of his time in political matters, being strictly independent in his views. He has, however, been a life-long member of several fraternal socities and a number of Masonic orders, and when he retired from lake engineering was made an honorary member of Midland Council, National Association Marine Engineers.

Mr. Taylor's private life is now spent at Goderich, where he resides with his wife and family on Lighthouse Street, his ability having descended to one son, who is serving in an engineering capacity with the Standard Oil Co. at Taft, California.

correcting such of the brush or mechanical troubles as may exist; or by shifting the brushes, or readjusting the commutating poles, or both; a brush having higher current density values and less susceptible to the effects of high voltages between the commutator bars should be installed. If a suitable brush cannot be had, the design of the machine itself may be subject to modification.

Honeycombing.—When brushes gradually burn away, forming small craters in their faces, they are said to "honeycomb." This is due to continuous sparking of a more or less hidden nature and may be either a slow or rapid nature. If the growth is slow, it is sometimes possible to correct it by increasing the brush pressure, thereby decreasing the contact drop and the contact arcing, and at the same time increasing the abrasive effect of the brush and grinding away the minute craters as they form. Honeycombing is due to the same causes, on a reduced scale, as glowing, and at times both may take place simultaneously on the same machine. Honeycombing has been traced directly to high mica in combination with loose commutators; also to improperly spaced main poles; and unequal air gaps; and in non-commutating-pole machines, to an abnormal shifting or distorting of the magnetic flux. The trouble is most frequently corrected by substituting a more highly refractory brush possessing abrasive characteristics.

Hardness.—Brushes have widely varying physical densities—some being very hard, others very soft. Very hard brushes usually carry a large amount of abrasive and have a low current density or carrying capacity. The softer brushes are more highly graphitic, carry abrasive to a limited extent only and have a high current density. The hardness or scleroscope reading is, therefore, indicative to a limited degree of the character of the brush.

Brush inertia has to do with the weight of the brush. The lighter the brush, the more readily will it follow the irregularities of the rotating element, and the more promptly will it respond to a given spring pressure. Again, the wearing on the commutator may not prove so great. If a light and a heavy brush prove equally satisfactory electrically on a machine, the lighter brush is preferable. If the materials from which brushes are made are heavy, it is advisable to have an increased number of small brushes, rather than a limited number of large brushes; also the spring pressures should be in excess of the pressures on lighter brushes having the same dimensions, and used for the same service.

Refractory.—Any material which resists the ordinary methods of reduction is said to be refractory. A brush, therefore, which resists wholly, or to a marked degree, high temperatures, such as heat generated by an electric arc, is said to be highly refractory.

Peripheral Speed is the speed in feet per minute of the face of the commutator or slip ring. Peripheral speeds which vary greatly require brushes having different characteristics. Generally speaking, carbon brushes are not so suitable for high peripheral speeds as graphite brushes.

HYDRO-ELECTRIC BUYS OUT ONTARIO POWER CO.

SIR ADAM BECK announced this month that the Hydro-Electric Power Comission of Ontario has acquired the assets of the Ontario Power Co. for $22,669,000 on the following terms:—

The company agrees to deliver all its Canadian properties, along with all its physical assets and contracts for the delivery of power, in return for which the commission agrees to pay in its own debentures to the extent of $8,000,000 for the $10,000,000 of stock now held by the company, and to assume the bond liability of $14,669,000 secured by a first mortgage on the property. The company is to receive the current assets and to assume the current liabilities.

The Hydro-Electric Commission will take possession of the property on the first of August. The municipalities will get their power at nine dollars per horsepower, and even selling power at that low figure it is estimated the plant would pay for itself in twenty-five years.

The principal owner of the Ontario Power Company was John Joseph Albright, of Buffalo, N.Y., who agreed to sell to the Hydro-Electric Commission ninety thousand shares of the company's stock at $80 per share. The shares have a par value of $100 each, and Mr. Albright has undertaken to accept as payment Hydro-Electric four per cent. forty-year bonds. There is now invested in Hydro property in this province practically seventy million dollars, including money put in by the municipalities.

Estimates made by the Hydro-Electric Commission's technical advisers, headed by Fred Gaby, chief engineer of the commission, show that the estimated revenue per annum from the sale of power is $2,396,277; the operating expenses, rentals, taxes, etc., will be $804,718; the fixed charges, interest on bonds, sinking fund, etc., will be $990,550; the total operating expenses, $1,795,268, leaving a balance of $601,009 for the year. From that will have to be deducted interest and sinking fund on the $8,000,000 worth of Hydro bonds, which will amount to $400,000, leaving a balance for depreciation of $201,009.

ELECTRIC HAZARDS*

By D. M. Petty.**

ELECTRIC hazards, accidents, risks dangers, or whatever one chooses to call the possibility of getting hurt by electricity, can be divided into four classes in general accordance with the way one is liable to receive an injury.

The first division is made by dividing all hazards in two classes according to voltage, namely, high and low voltage hazards. Each of these two divisions may well be divided into two classes according to the manner in which the injury is received, namely, shocks and burns.

With low voltage we hear more of burns than of shocks, while with high voltage the reverse is true. It is also true that while there are many more low-tension shocks than burns, they are not so serious, while with high tension a shock proves fatal much more often than the burns with low tension.

Shocks From Low Tension

Personally I do not know of a single case of persons being shocked to death with less than 300 volts. There are, however, cases on record where men have been shocked to death by 110 volts. The doctors tell us that a man with a weak heart is in danger when receiving a 220-volt shock, and it is well for us to believe it. We can, however, say that 220 volts will not endanger the lives of men when working on a dry wood floor, unless the man gets good contact on both sides of the line. We can also say the same thing with a little less margin of safety of a dry concrete or tile floor. A metal or wet earthen floor, however, provides a good contact for the man standing on it, and he is in much more danger. So far as shocks are concerned with 220 volts, we may consider men as normally safe, and extreme precautions are not necessary.

Burns From Low Tension

Burns from electric arcs may be divided into two general classes. The first are those caused by short circuits or ground, occurring during construction or repair work. A burn of this kind most frequently comes from accidental contact with both sides of the line with a screw-driver, pair of pliers, or other tool when an electrician is making a connection.

The hazard in this case is directly dependent on the man. A careless man will get burned often, while a careful man will work for years without a single accident.

It would be extremely conservative to forbid connections, disconnections, or repair work on 220 volts and lower when alive, and the writer does not feel it is necessary or even a desirable step to recommend. The only means that will prove really beneficial to the man, the apparatus and the company for whom he works, is care. Train the electricians to be careful.

The second class are the burns which occur in the vicinity of open fuse blocks. These blocks are usually spaced close together and often on the live side of the switch. The object of putting fuses on the live side of the switch is to protect the circuit against a short circuit in the switch, but these are so infrequent that it is better to arrange the fuses on the dead side of the switch.

Prevention of Accidents

As to prevention of this class of accidents, the following suggest themselves as remedies: Train the men to be careful. Eliminate as far as possible work on live parts, such as fuses, by putting the fuse

*Proceedings of Fifth Annual Safety Congress, National Safety Council.

**Superintendent Electrical Department, Bethlehem Steel Co.

on the dead side of the switch. Use tools with insulated handles where possible. Use enclosed fuses in place of open link type. Use circuit breakers.

The second class of burns differs from the first more in the nature of the men who are burned than in any other point. They are not the electricians, but the shop and mill men. This class includes short circuits in hand lamps, lamp cords, lamp sockets, rosettes, and now and then a bad fuse.

The following "Dont's" would help to reduce accidents from this hazard:

Don't put in a fuse unless you know why it burned out. Call the electrician.

Don't drag extension lamp cords around on the floor.

Don't play with switches.

Don't try to "fix" the motor or the lights, let the electrician do this—it is his job.

At this point it is well to take up the much-discussed question of enclosing low-tension circuits.

Few, if any, men are killed from the shock of 250 volts or less. Most men who lose their lives, due either directly or indirectly to shocks, receive such shocks from trolley wires in some elevated position and fall some distance.

Burns usually come from some attempt on the part of the man burned or a fellow workman to repair or adjust live parts.

It would seem, therefore, that there is no necessity for going to any great extreme in totally enclosing low voltage. Because:

1. Parts that need adjusting or repairing must be uncovered before such repairs or adjustments are made, and the same hazard for a short would exist after enclosing as before.

2. Trolley wires and such bare lines cannot be enclosed without making it very difficult to instal or repair same.

It seems to the writer that the proper course to follow is what may be termed a "middle course"; that is, enclose parts that the machine operator must handle to properly do his work and design the rest of the layout to avoid short circuits to the electrician and forbid others handling in any way this part of the apparatus.

Take, for example, a motor-driven lathe as a typical machine:

Following in through the power lines, we come first to the circuit breaker. By properly locating this and by using a design with both sides of the line separate, it is unnecessary to enclose it even in an iron box. The arcing tips should be so arranged that the arc flies up, and should a short circuit exist in the wiring, by closing one side at a time the breaker will open when the second leg is closed and will not hurt the operator.

Next we come to the controller, which is usually located in an out of the way place, and must be enclosed for its own sake.

Then we come to the motor, which is usually of the open type. If the operator is allowed to adjust, or, rather, as the case usually proves, disadjust the brushes, he will at times receive shocks and may get burned by short circuiting a tool of some kind from one brush holder to another of opposite polarity.

If magnetic or so-called automatic starters are used, it is not necessary, unless desirable from a "dirt" standpoint, to enclose the contractors or resistors.

High Voltage

In passing from low tension to high tension, the character of the hazard changes with increasing potential from burns to shocks. From 440 volts up the shock is to be considered dangerous, and while it may be said that a fairly small percentage of those receiving shocks of even 500 volts are killed, yet the fatalities are high.

Shocks from high voltage may be divided into two classes: Contacts with bare parts of a circuit; breakdown of parts supposed to be insulated.

In the first class come contacts with transmission lines, which are and should always be run with bare copper, busses in the power stations, choke coils, switch parts, etc. A large majority of these shocks are due to the old excuse, "Didn't know it was loaded," and are properly classified as carelessness.

All high-tension apparatus should be, and usually is, built so as to prevent the man from handling live parts when things are in normal operation, and it is seldom, if ever, that a man is shocked to death under these conditions.

Repairs and Adjustments

Most danger lies in making repairs and adjusting apparatus and in so-called temporary work. One of the greatest contributing factors in this dangerous work is some man throwing the wrong switch, energizing a circuit or wire on which other men are working.

The parts being worked on should always be carefully grounded.

One man should attend to the closing of switches.

One man should have charge of the job in hand.

When working on live parts, a carefully designed barrier will prove effective against the opposite polarity, and a well-insulated platform should be used to work from.

Rubber gloves are unreliable and should be used with great care. They may be used for pulling line fuses, etc., where a proper hook stick is also used.

In the second class of high-tension hazards, both the electrician and the operator are subject to the danger of some part of the insulated circuit breaking down and charging a part of the apparatus that is normally safe. One of the most dangerous points in this connection is the step-down transformer. The high-tension primary may break through the insulation and charge the low-tension secondary with high voltage, and thus impose high where only low tension is supposed to be.

The manufacturers as well as users of transformers have always paid a great deal of attention to this one point, and it is seldom a break occurs outside the test room of the manufacturers or during a lightning storm.

When we have discussed shocks from high tension, the hazards of that division are almost covered, for while we may have shocks without burns, it is almost impossible to have burns without shocks on a high-voltage circuit. Contact with both sides of the line is less liable to happen on account of the greater spacing of parts with high tension and the current available to make an arc is less than with low tension. Reduction of accidents in the electrical field is dependent on the extent to which we can impress the men to be careful and is, therefore, no different from other lines of work.

There is one more point, however, that should be brought out very strongly for the benefit of the workmen rather than the electricians, and that is to let electrical apparatus and wires alone. When there is trouble, call the electrician.

NIAGARA FALLS POWER CO. REPORT

THE pamphlet report of the Niagara Falls Power Co., for the year ending Dec. 31, 1916, says that all permitted means have been taken to meet the rapidly-increasing demand for power. Two additional generating units in the Canadian plant have been completed and placed in service. A third unit is now in process of being added. The management points out that the rapid increase in power use in Canada has led the Government to reduce considerably the permits for the exportation of Niagara power, and adds:—"The export license of our Canadian company has been reduced from 75,000-horsepower to 30,000 horse-power. We have, therefore been obliged to withdraw 45,000 horse-power from American industries, despite insistent demands."

ELECTRICAL QUERIES AND REPLIES

Question.—Define the terms Volt, Ampere, Ohm, Watt, and explain their relationship to electrical horse-power?—M. A. C.

Answer.—The volt is the unit of measurement of force, or strength of electric current, commonly known as electromotive force, or E.M.F. The ampere is the unit of measurement of electric current quantity. The ohm is the unit of resistance to a current passing through a unit length of wire of unit diameter; and the watt the product of one volt and one ampere = volts × amperes. An electrical horse-power = 746 watts, which is equivalent to that of the steam engine, viz., 33,000 foot pounds.

* * *

Question.—What means are employed to prevent any part of an electrical circuit from becoming overheated?—P. H.

Answer.—A fusible cut-out or fuse which consists of a strip of lead or other readily melted substance is introduced at a convenient point. Then, if from any cause the current becomes greater in intensity than the lead and its connections can comfortably and safely stand, the fuse owing to its resistance becomes overheated and melts, thus breaking connection and preventing overheating of parts in the circuit beyond.

REFRIGERATION DEPARTMENT

DIFFERENCES IN QUALITY OF AMMONIA*

By A. Johnston

MANY users of ammonia imagine that "Ammonia is Ammonia"—meaning that as far as they are concerned, all brands of ammonia are alike in quality, possibly because all brands smell so pungently strong as to divert the mind from any other quality, except the odor, leaving all thoughts of other factors so necessary to efficiency, in the background. "Ammonia is Ammonia"—which of course is not true as can be proven by the late report of the U.S. Bureau of Standards, as read before the American Society of Refrigeration Engineers in New York City last December. They did not jump to conclusions for it required several years time to study, test and report on eight different American makes of commercial anhydrous ammonia direct from the original cylinders. All contained impurities, some more than others; for instance the amount of volatile carbonaceous matter (which is a very harmful impurity even though in small quantities), was present in every one of the eight brands—only some had much less than others.

Differences in Ammonia

Why such differences should occur can partly be explained by the various methods of manufacture by the eight different makers. Each one thinks he has the best apparatus and process and that is quite a natural thought. Then again there are two widely different methods of making ammonia—one is called the "sulphate process"—the other is called the "direct process." To briefly explain:—The sulphate process depends on using salt called sulphate of ammonia. The ammonia gas contained in the crude gas house liquors is absorbed in sulphuric acid and in forming itself into a crystal is subjected to nature's powerful purifying process—the crystals are then converted into a very uniformly pure ammonia gas and sold to the public.

The "direct process" distills the ammonia direct from the crude gas house liquors without going to the troub e and expense of crystallizing it in sulphuric acid to remove impurities. It is a cheaper and quicker process, and is the common process in use to-day. Some day we may add another process called the synthetic process which produces ammonia bv snatching the raw materials from the atmosphere and water, this is not yet in commercial use so we will not dwell on this "air snatching process," except to mention it as a future possibility.

In addition to the two widely different processes, each maker no doubt has little inventions of his own, brought about by experience, troubles and necessity—so that it is not to be wondered at that a volatile product like anhydrous ammonia should differ in quality. Think how difficult it is for eight differently constructed distilled water ice plants in eight widely separated districts, under eight different engineers, to even make a non-volatile product like distilled water come out the same—for instance—some would be better than others, some would have oil in it—some would have air in it—some would be colored red, yellow or green—when frozen some would have a bad taste, due to bad arrangement of steam condensers or naturally bad weather—some would have no oil, odor, no r bad taste in the water.

Personality and Ammonia

The foregoing may be claimed to be due to the element of the personal equation because some men can make sweeter and cleaner distilled water than others—which is quite true, and the same argument holds doubly good in the art of ammonia manufacture, for ammonia is a highly volatile compound and must be kept within pipes or closed vessels, whereas distilled water is liquid under ordinary conditions and can be examined any time and is more easily made.

If then, it is so hard to make ordinarily distilled water alike, how much more difficult it must be to make all ammonia alike in quality, yet some people still believe that all ammonia is alike, not only operating engineers but even consulting engineers who are supposed to use their heads instead of their hands.

Each manufacturer naturally swears by all the prophets that his ammonia is "the best," that meaningless and timeworn expression—"the best," means nothing, for every one knows that all the shades of quality are disguised as "the best" and there is nothing to prevent any maker claiming it, whether it is so or not—that occurs not only in the ammonia line but in other lines.

The old time evaporating test with a bottle has been found to be no criterion as to purity of the gas but is very good to find such things as water, oil or other non-volatile matter. The volatile impurities pass out of the test bottle and are lost in the air. The working test is the best but you should always show enough interest to find out by which process your ammonia is produced, whether by the sulphate process or the direct process, or whether made by a teamster or a chemist, or any other point you can ascertain, preceding the manufacture, not afterwards. Any or all of these points have some bearing on the quality expected in such a highly volatile product.

You will find that a "sulphate made" ammonia is more uniformly pure and comparatively free from harmful carbon compounds if properly made. All ammonia will refrigerate more or less, but when it contains carbon impurities its efficiency is reduced and high power bills created. High power bills waste dollars and cents.

Ideal Pure Anhydrous Ammonia

The ideal pure anhydrous ammonia should consist of two colorless, tasteless and strange to say, of two absolutely odorless gases, called nitrogen and hydrogen. (One is the laziest, the other is the most active gas—chemically speaking). The odor is created when these two gases are united in a fiery furnace. When the time comes that ammonia is heated until these two constituent gases separate, they lose the odor, but the ammonia was spoiled by heat, so you see there can be no odorless ammonia, at least for a while. The odor cannot, however, make ice; it has its function, nevertheless, which is to indicate by smell, any small leak.

Another strange thing is that when you dis-associate your ammonia gas by great heat, it increases its volume 100 per cent., and is not condensable. It doubles in volume so it is no wonder the the high pressure climbs upward under such conditions. No one can explain why the volume doubles, we only know it occurs by heating. A good pure ammonia should stand any heat necessary in an ice plant without being spoiled.

Many operating engineers have specified "sulphate made" ammonia and received the ordinary direct distilled ammonia just as many a piece of steel pipe has been sold when iron pipe was specified; all because the user was not careful to see that he got what he specified. If any engineer is alert and smart enough to obtain beneficial efficiency from some particular quality, hard-hearted boss will buy it for him and thank him for being so wide awake. It is the "sleepers" that cannot get what they want from the boss. Do not forget that the wide awake engineer sees more, knows more, explains more and gets more from his employer, in addition to certain added confidence and respect from everybody else. The sleepers get only what is thrown to them—so be a propellor not a drag to your business of making the plant earn money. Keep yourself

*From paper read before the Virginia Manufacturers' Association.

posted by reading your trade journal carefully. If you do not now take a trade journal, then subscribe for one at once, nothing is so disheartening as to find a good man groping about in the dark, surrounded by ignorance and superstition adopting erroneous ideas and guessing at results. Such a man might say "ammonia is ammonia" and believe it all his lifetime.

EXHAUST STEAM ABSORPTION MACHINE EFFICIENCIES*

By B. F. Kubaugh

UNDER this title an attempt will be made to indicate briefly the performance that may be expected of the exhaust steam absorption machine as an isolated distilled water plant; and in various combinations with power or lighting, and compression plants.

In the isolated exhaust steam distilled water plant, we employ auxiliary pumps, either direct steam driven, or engine driven, as required by circumstances. The exhaust from the auxiliaries or engine passes into the ammonia generator under a comparatively low pressure where it is condensed and is afterward skimmed and used in the cans. The quantity of steam condensed by the ammonia generator is more or less fixed, or varies within small limits, and as it is essential that the quantity of steam supplied by the auxiliaries should come within the requirements of the generator, the method of driving them is varied, being direct steam driven for cold water machines, and engine driven for warm water machines.

It has been found that the steam required by the auxiliaries is less, if anything, than that required by the generator, so that it is safely assumed that the total amount of steam required to drive them and to generate the ammonia is represented by the steam consumption of the generator. This varies from 56 to 60 pounds per ton ice per hour, but as 96 pounds of water per hour are required to produce a ton of ice, the difference, or 40 pounds, is made up by a multiple effect evaporator, the condensation from which goes to the distilling system, and the vapor from which is condensed in the ammonia generator together with the pump exhaust. The relation between the quantity of vapor so required, and the condensation, determines the number of effects to be used. This will rarely be less than two effects, nor more than three, for, as stated before, the methods of driving the auxiliaries can be varied so as to require a practically constant amount of vapor from the evaporator.

Evaporator Range of Pressures

The evaporator under this system operates through a wide range of pressures, from the boiler on the initial side to the pump exhaust pressure on the vapor side, and, as it does not require an initial pressure in excess of 100 pounds, can be installed in connection with boiler equipment previously built for this (now) low pressure, thus converting old live steam machines into much more economical exhaust steam types. With this type of machine can be produced 1¼ pounds of ice in the storage room for every pound of steam generated in the boiler, or 25 per cent. more ice than steam. This means that, with a horizontal tubular boiler producing seven pounds of steam per pound of coal, a productios can be obtained of 8¾ tons of ice per ton of coal. With water tube boilers, producing eight pounds of steam per pound of coal, an ice production of 10 to 1 can be obtained. The plant of the Hygienic Ice Co., of Birmingham, Ala., is so equipped and has produced 10½ tons of ice per ton of coal. For small installations where water tube boilers would not be justified, steel encased tubular boilers with shaking grates by their increased economy over the brick-set boiler will increase the production per pound of coal over that given above.

Pure Ice Production

For the production of pure ice free from contact with oil at any stage of the process, the absorption machine occupies a field of its own. In this system, the auxiliaries are of the centrifugal turbine driven type. A plant of this type was installed during the past year for the Crystal Ice Co., Richmond, Va., in collaboration with their manager and chief engineer, J. C. Kent. This plant consists of three 45-ton machines equipped with exhaust steam ammonia generators, replacing live steam generators of the vertical spiral coil type. Part of the old equipment was retained, only that part connected directly with the utilization of exhaust steam being new. The auxiliary equipment consists of one 6-inch and one 8-inch double suction Platt centrifugal water pump, each direct connected to Terry turbines, guaranteed to operate at 77 pounds of steam per horse-power hour with 100 pounds initial and 20 pounds exhaust pressure; one 37½-kw. generator, direct connected through gearing also to a Terry turbine. This generator operates four propellers in two of the three ice tanks; one 8-inch centrifugal pump for circulating in the third ice tank, which could not be equipped with propellers; three 1½-inch centifugal brine circulating pumps; one 6 x 6 Sullivan air compressor for operating the hoists, which it was not desired to chasge. The current consumed for all brine circulation and air compression amounted to only 16 2-3 kw. or about 25 horse-power at the turbine. This, together with the exhaust from the turbines in the water pumps, furnished very nearly enough steam for the ammonia generators. When running at full capacity it was necessary to bleed in some live steam, but when running only one or two of the machines the turbine exhaust and generator consumption just about balanced.

To quote one of Mr. Kent's letters, he says: "Our steam is free from any oil and as pure as can be made. We have not lost a block of ice from oil contamination." He states further that in spite of the handicap of a cool season, allowing full capacity during only one month and running under capacity the balance of the time. "We, however, have made 54½ per cent. more ice per ton of coal this year than last. We cannot see how the most economical engine could have increased our economy."

Combination With Power and Lighting Plants

The combination of the absorption machine with power or lighting plants for the production of distilled water ice has been accomplished with very satisfactory results. The usual method is to operate the ammonia generator with the exhaust from the original auxiliaries to which is added the exhaust from the additional auxiliaries required by the ice plant, such as ammonia pump, brine circulating pump, brine agitator etc., The exhaust from these pumps, more frequently than not, supplies less steam than the generator requires and a small quantity of live steam must be added to make up the deficiency. As the total amount of steam thus utilized in the generator in the production of the necessary refrigeration amounts to only 58 per cent. of the total required for the ice, the remaining 42 per cent. is recovered by means of a condenser from the exhaust of the power or lighting engines at atmospheric pressure. In cases where the power or lighting engines are run only periodically, the steam condensers are made extra large and tanks are provided for obtaining the distilled water when available and holding it in storage to be fed through the cooling and filtering apparatus as required.

Typical Example

Among a number of plants of this kind, mention may be made of a 30-ton ice making equipment installed in the city of Fernandina, Fla., in connection with the municipal light, power and water plant. In this case the water pump supplied the city, having a capacity of two million gallons daily and of course the exhaust from this pump could not be used directly in the ammonia generator, but a portion of it, together with the exhaust from a 100-hp. Ball & Wood and a 150-hp. Skinner electric generating outfit, was condensed in a steam condenser and fed to the cans through the usual skimming, reboiling, cooling and filtering apparatus. Ice is made in this installation at a cost in fuel and labor of only 43 cents per ton and sells at prices ranging from $4.00 per ton in single 300-pound blocks to $6.65 per ton in five-cent pieces. The real or legitimate cost of the ice in this case is considerably under the figure given, which includes the cost of steam really chargeable to the electric light plant. This price also is figured on coal at $3.30 per ton.

PROPOSED SECRET SESSION OF BRITISH ENGINEERS

APROPOS of the recent registration of Canadian engineers, at least those constituting the membership of our various Technical Societies and Associations, with a view to their services being made available to the Government either in consulting, administrative, or research capacities, a unique proposal has been made to secure a secret session of Old Country engineers, at which a representative of the British Admiralty would explain the means being taken to combat the submarine menace, and detail as fully and clearly as possible such problems connected therewith as yet remain unsolved. While it is realized that the Imperial Government can command, and has at its service, no end of what are believed to constitute the best scientific brains available, it is more than probable that much brain wealth is outside the fold. Our British contemporary, "The Engineer," very aptly remarks when discussing the subject that "useful inventions frequently spring from quite unexpected quarters, and that if the brains now officially at work have failed to solve the submarine problem, it is time others were tried, and high time that new fields of thought were explored."

The secret session proposed would be organized and managed by some such body as the Institution of Civil Engineers, the individual members to include men drawn from the country's principal engineering and shipbuilding establishments to the number of say three or four hundred, and of whose ability and integrity there could be no doubt.

PLANT REFERENCE LIBRARY

A FACTOR likely to have considerable bearing upon the increased productive power of manufacturing plants, would be the establishment of a works library, in which a quantity of technical books and other literature would be available for ready reference for those officials who might be confronted with difficult problems pertaining to their particular class of work. These libraries would not require to be stocked with a wide range of subjects, but preferably a quantity of books and periodicals containing a comprehensive record of previous and current practice in the particular lines of activity in which the various plants are engaged.

While the available books would be primarily for reference purposes by the various department heads, the opportunity should be provided for the loaning of these books to any employee desiring same for study. By encouraging the workmen to take a greater interest in the technical features of their daily labors, it would not only increase their productive efficiency but also their earning power; and at the same time provide a means of developing trained men who would take a keener interest in the work they are doing. The returns from a reference library of this nature should more than repay the expense entailed by installation and maintenance.

THE COMING C.A.S.E. CONVENTION AND EXHIBITION—A SUGGESTION

THE generally central location of the City of Toronto from an industrial and manufacturing standpoint leads us to anticipate a record attendance of power plant engineers at the C.A.S.E. Convention and Supplies Exhibition to be held there from July 24 to 27 inclusive. As an excellent "menu" is being provided—business and pleasure, for each day and evening, it has been suggested to us that the local executive in charge of the Convention Souvenir, would, by mailing or placing the latter directly in the hands of all engineers within a reasonable radius, say a week or ten days in advance of the coming function, not only confer a favor on the makers and dealers in supplies and equipment who will exhibit, but eliminate the tendency to indifference more or less apparent in past years to the value of and benefits to be derived by participating in this annual gathering.

The Operators' Point of View

OPERATING UNDER ADVERSE LOCAL CONDITIONS

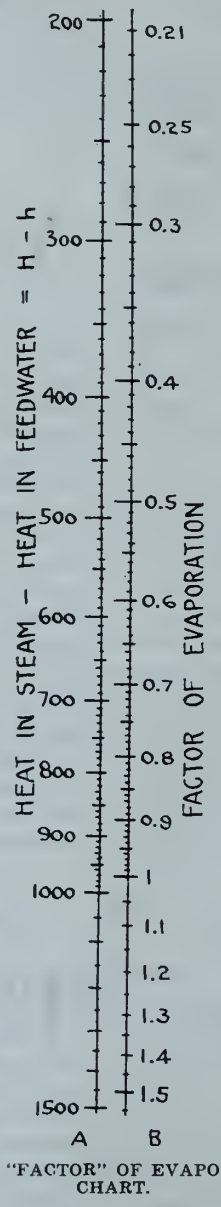
By W. M. Grey.

HAVING had considerable experience in operating power plants, both in the east and west of Canada, perhaps the following would be of some interest to readers:

Taking charge of a plant in the west two years ago, which consisted of gas engines and auxiliaries, of which vacuum pumps and air compressors formed a part, there was some difficulty in keeping a uniform regulation of vacuum and compressed air, which was caused through the high altitude. I might say the altitude at this point is about 2,500 feet above sea level, and variations in atmospheric conditions were noticeable on vacuum gauge and air gauge. This was not a condensing plant, the vacuum being used for the suction of molten glass from a revolving pot at a temperature of about 2,000 degs. F.

The best vacuum obtainable here has been 24.5 to 25 inches, compared with 28 inches in the east for the same manufacturing process, and it naturally makes a big difference in production between plants in the east and west of Canada. The gas engines installed were Bruce McBeth four-cylinder high speed units, belt-connected to two generators, and run on the 24 hours' system. There was also some difficulty in keeping engine jackets cool, the nearest water supply being 2 miles away from the plant, it was necessary to instal water supply tanks with the object of using the same water over and over again in order to get rid of the impurities which consisted of alkali and lime. Owing to the high altitude, and the natural gas in that part of the country, which seemed to develop a high and dry temperature, it seemed utterly impossible to keep cylinders cool, and cylinder heads, which are about the hottest part of the engines, would get steam bound. The only remedy for this at that time was running hot water off the tanks and admitting more cold water to make up the difference. This remedy was all right as far as cooling off was concerned, but only made matters worse in respect to scale conditions. Cylinder heads were taken off the engines after being in service for one month, and the water parts were completely choked off with alkali and lime. Boiler compounds were of no use, as one could not allow the water to get hot enough to enable the compound to do its work. The cooling surface in the cylinder heads being very small, especially in between the gas and exhaust valves where the water passage is only one-half inch wide, this passage would fill up with scale causing unequal expansion and contraction and end up with a cracked cylinder head.

During 20 years' experience in operating gas and steam electro plants this particular plant is one of the best I have ever handled as far as its machinery is concerned, the Bruce MacBeth gas engines are an up to date unit and in my opinion come next to steam engines for steady running, but like all other types of gas engines must have good local conditions in order to obtain good results.



HANDY "FACTOR" OF EVAPORATION CHART.

The object of this article is merely to express our opinion of operative conditions in the east and west of Canada, namely altitude and impurities in water. No doubt some local conditions can be overcome by going to some considerable expense which would eventually pay for themselves.

FACTOR OF EVAPORATION CHART

By N. G. Near.

THE term "Factor of Evaporation" is used a great deal in engineering — so much the writer thought it worth while to work up a chart on the subject in order that anybody can reduce ordinary heat values directly into factors of evaporation without doing any figuring.

For example, you look into your steam tables and find that the total heat in steam at a given pressure is 1,100 B.t.u. You also find that the feed water originally contained 100 B.t.u. per pound. The difference H-h is therefore equal to 1,000 B.t.u.

Find the 1,000 in column A and directly opposite in column B is the factor of evaporation. You can see that it is very close to 1.03.

The figures above 1,000 in column A, are seldom used. They are used sometimes in connection with feed water heater computations, however, and in order to make the chart more complete, I therefore included them also. Thus, where the difference in heat values might be 300 B.t.u., the factor of evaporation is immediately given as 0.31.

TURBINE GEAR LUBRICATION

By O. C.

WITH the increased use of geared drives there is an increased necessity for minimizing friction, thus reducing the wear and noise and increasing efficiency. The best results so far have been obtained with helical gearing, and the use of this has proved extremely advantageous in the case of turbine drives for marine purposes and for direct current generators. The latest types of double helical gears are, however, those which secure the best results, great accuracy being combined with high efficiency and silent operation. The mounting of all gearing should have extra careful attention, especially as to the support of the pinion in high speed and high power work.

The lubrication of turbine gears is effected by means of special sprays arranged to deliver the oil direct on to the teeth, as to allow such gears to run par-

tially submerged in an oil bath would absorb an appreciable amount of power. The pinions of turbine gears are usually of nickel steel, and the large wheels of cast iron with steel rims. To obtain quiet running, straight-cut rawhide, cambric and paper pinionss are sometimes used; ordinary hydro-carbon oil, however, is most destructive to rawhide pinions, and the fact that rawhide pinions have gained a bad name is entirely due to the use of this lubricant. One of the best compounds for rawhide pinions is as follows:—

Plumbago	15%
Resin oil	55%
Resin	30%

UTILIZATION OF PEAT AS FUEL

By T. J.

UNTIL recently there has been no system in existence for the utilization of peat on a commercial basis; but a new invention, which recently reached the commercial stage, offers a means of supplementing the existing coal supply and in the meantime providing an ideal charcoal for the trenches. The whole trouble with regard to the utilization of peat has arisen from the difficulty of completely separating the moisture from the solids. It was this difficulty that all inventors had failed to overcome. The process here referred to, known as wet carbonizing, solves the problem. It is simple and works almost automatically. The peat is pumped from a bog into a reservoir, then fed into tubes, which are steam-jacketed and heated to such a high temperature that a complete chemical decomposition takes place in the peat, and the tiny cells are completely disintegrated; in other words, the water and peat become two distinct elements. The remaining process consists in pressing the water out and drying the peat powder before making it into briquettes. The briquettes contain a fair percentage of nitrogen, and are of a high calorific value.

HOW THE MOVING PICTURE FILM GETS ITS MOTION

By D. A. Hampson.

A MOTION picture film is a celluloid strip about 1½ ins. wide and hundreds or thousands of feet in length, crowded its whole length with thousands of small negatives, just the same as would be made in a little camera of ¾ in. x 1¼ in. size. There are sixteen of these negatives to a foot of length, and so rapidly have they been "snap-shotted," we will say, that a careful observer can see little if any difference between any of the sixteen in a given foot; it is only when a comparison of negatives quite a distance apart is made that a difference is noticed and one begins to comprehend that a progression is occurring and a scene is being unfolded.

The person who, for the first time observes what slow progress he makes with a scene when looking over a film in his hand, cannot fail to appreciate the rapid rate at which the film must run through the projecting machine in order to reproduce the scene in a life-like manner.

Not a Magic Lantern

Most of us have a general idea that this machine is a sort of glorification of the magic lantern of our youth brought up to date by electricity and mechanical

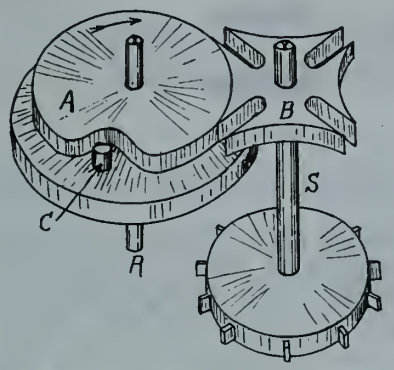


FIG. 1. DETAIL CONSTRUCTION OF GENEVA STOP MECHANISM.

movements so wonderful that it takes a skilled operator to run one. It is very true that if a film is in the machine and is held stationary, a picture from that negative will be thrown upon the screen just as would one from our primitive lantern slide—a noticeable difference being that the film is run through in and up and down direction instead of horizontal. Moreover, in the modern machine the firm travels at a rate that carries about 800 individual negatives per minute through it—a rate so high that without some very ingenious mechanism intervening there would be nothing but a swath of blur moving down the screen. What, then, is this mechanism that rises superior to blur and high speed and countless pictures having no perceptible difference?

What is called a "Geneva" gear is the important part of every projecting ma-

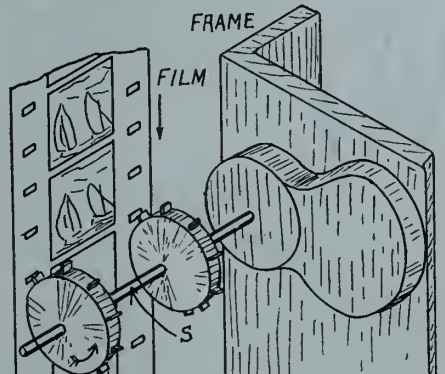

FIG. 2. SHOWING ARRANGEMENT OF GENEVA STOP MECHANISM AND FILM.

chine; it is a motion that (through the aid of other parts) draws the film along, stopping it momentarily when each picture or negative is in front of the lamp only long enough to allow a clear enlargement of it to be thrown on the screen and then, with a jerk that is discernible to the spectator only as a slight flicker, draws it just the height of another negative and brings it to a positive stop. This is done eight hundred times a minute, thirty minutes at a stretch, and always ready for the next roll. This Geneva gear is indeed a triumph, but not a modern one except in its refinements, for in textile mills we find looms bearing a date long "before the war" that are still doing business with the original Geneva in a fair state of preservation.

Action of Geneva Stop

Referring to the drawing, R is a shaft driven at a constant speed all the time, carrying one member of the Geneva gear A, which through the pin C drives a member B on the shaft S, which in turn draws the film through the machine. But while the shaft R revolves four times, the shaft S has made but one revolution and during that one it has been started and stopped four times—this is the motion that is transmitted to the film.

The member A is a disk whose periphery is broken for a short section opposite the pin C, which is rigidly set in the flange of the disk. Concave faces on the member B rest against the periphery of A, and during this period of rest, the shaft S and the film are stationary. Between the concave faces are slots, and as the disk A revolves, the pin C runs into one of them, moving the (so-called) star wheel B a quarter revolution. The movement of B is only possible because of the cut-out section of A opposite the pin. This is the motion that runs so faithfully hour after hour. Of course, the materials have to be of the best, the gears run in oil, and the shafts set for perfect meshing of the parts: in its present perfected state it looks very simple. The gear and shaft ratio is varied on different machines, but the one shown of one to four is generally used.

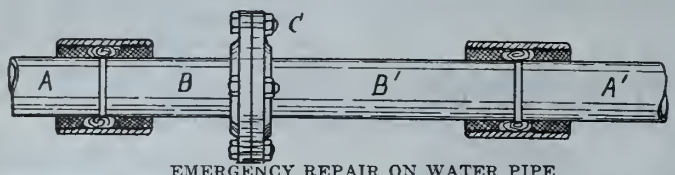
Location of Stop Gear

To make the working of the machine a little more clear, a part of the related mechanism is shown in Fig. 2. Here is shown a portion of the main frame of the entire machine, and also the oil-tight case enclosing the Geneva gear. The same intermittent shaft S extends out from the case and carries on it two sprockets which have a special form of teeth engaging holes in the film. There is a row of these holes of exactly the same spacing on each side of every film made and it is by means of these holes and sprockets that an accurate, positive movement of the film is obtained from the equally positive Geneva gear. This describes the salient features of the motion picture projecting machine of today; there are gears and lenses and lamps and fire shutters, but they are of only passing interest. It might be added that one of the heaviest losses of the films themselves occurs from tearing, which comes from the action of the metal sprocket teeth jerking the light strip of celluloid. A torn film is valueless and though inventors have worked on some other forms of positive drive, they have so far been unsuccessful.

EMERGENCY REPAIR ON WATER PIPE

By John Port

A CAST iron water pipe, 4 in. in diameter, carrying water at 80 pounds pressure, cracked, and a section five feet long



EMERGENCY REPAIR ON WATER PIPE

had to be cut out. There was no cast iron pipe on the job, but a couple of short pieces of 4 in. wrought iron pipe, a 4 in. flange coupling, and two 6 in. pipe couplings were looted out. The two short pieces, of pipe were connected with the flanges C. the couplings were slipped on and back over the ends of the cast pipe ends A.A[1]. Then the 6 in. couplings were drawn back over the pieces B.B[1], after they had been put in place.

Oakum packing was driven into the couplings, as shown by the section, and lead joints run and caulked in the usual way. There is nothing extraordinary in this repair, but it just shows that there is generally some way to overcome a difficulty. In this case lack of cast iron pipe and sleeves did not prevent the man in charge making a proper and permanent repair.

EMERGENCY MEASURING METHODS

By T. Sim.

OFTEN when a man should have a measuring rule with him on some job, he discovers that he has laid it down somewhere and forgotten to take it up again, or perhaps it has fallen out of his pocket. Usually he will "curse" or "bless" his luck, and return to the work-

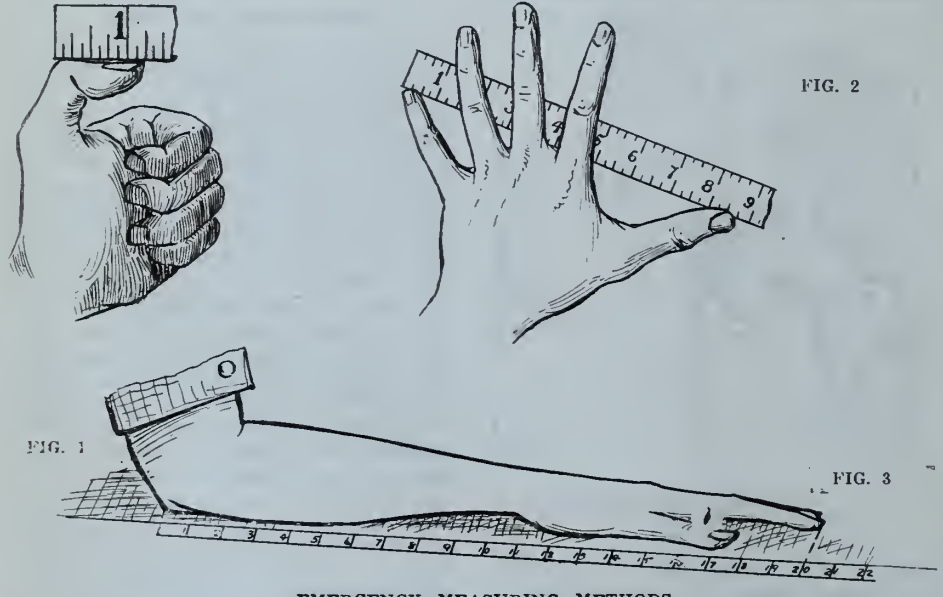


FIG. 1

FIG. 2

FIG. 3

EMERGENCY MEASURING METHODS

shop for a "rule." There are a number of ways for taking measurements with things that are always with us, and other things usually with us. These measurement things will give us approximate measurements only, unless we use considerable care, but if a little trouble is taken to memorize the tips here given, they will often come in handy.

The Dominion $1 and $2 bill is 7 1/16 in. long. An American or Canadian "quarter" is very close to 1 in. in diameter.

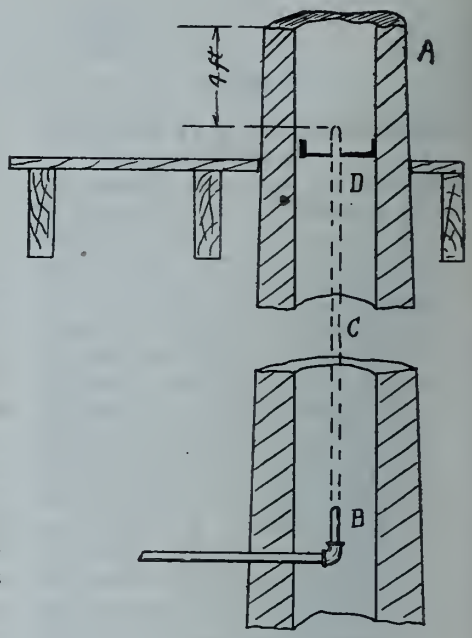
Look at Fig. 1. The upper joint of the averge female thumb is usually very close to one inch. In the average male it is about 1⅛ to 1½ in. The old hand outstretched measure, as shown in Fig. 2, will come close to 8¼ in. in the male. Fig. 3 shows the forearm measure—from the point of the elbow to the tip of the middle finger will be about 20 inches in the adult male and 16 inches in a female. No doubt most readers have seen the store ladies stringing yards of lace or other material, by stretching the material from the chin to the tip of their outstretched hand.

It is a good idea to ascertain the length you take while walking. If you have a knowledge of this, it is an easy matter to figure any distance required by counting your steps. Many men can pace or step off any distance, taking three feet to the step, and come out at the end very nearly correct. A little practice will enable any man to do this with a fair degree of success.

A DRAFT KINK

By John Ellethorn

SOME years ago, the wind blew down part of the stack in a certain building at works where the writer was employed, breaking it off a short distance above the roof. As business was very brisk in this department at the time, orders were given to install a steam jet. The writer did so as shown at B. Fig. 1. This helped some, as the draft showed a decided improvement. However it was still difficult to keep the steam pressure up to the desired figure. As an experiment a length of one inch pipe was attached to the nipple at B, this brought the end of the pipe to within four feet of the top of the broken stack, as shown by the dotted line C. The top end of the one inch pipe was closed in, by heating and hammering, leaving a 3-16 inch hole for the steam to escape. It proved so successful that it was still doing bus-



DRAFT KINK DETAIL

iness when the writer left some months later. A brace, D, held the pipe central in the stack.

No claim is made that this kink will save any fuel or check the smoke. The jet was controlled from a valve, placed handy for the fireman. The quantity of steam the jet will use when discharging into the atmosphere can be found by Napier's rule.

$$W = \frac{pa}{70}$$

Where

W = Weight in pounds per second;

p = Absolute pressure in pounds per square inches;

a = Area of orifice in square inches.

This kink is not recommended as a permanent affair, it is simple and handy in an emergency. A fan will require less steam and give the fireman better control over the fire, but fans have their drawbacks also.

HANDY RULE FOR FINDING CONTENT OF CYLINDRICAL TANKS

By C. T.

THE following table is useful in arriving at the contents of cylindrical tanks placed horizontally, i.e., with the two circular ends standing vertically. The diameter referred to is one passing vertically through the centre of the circu-

lar end. The table can be used for finding how much has been run off (up to one half) if the percentage of the diameter be counted from the top of the diameter. If the measurement along the diameter be made from its bottom end, the quantity remaining in the tank, (up to one half) can be at once found.

HORIZONTAL AND CYLINDRICAL TANKS
CAPACITY IN PER CENT. OF DIAMETER.

1%	of diameter is	0.0017	of capacity.
2%	"	0.0048	"

30%	"	0.2523	"
31%	"	0.2640	"
32%	"	0.2758	"
33%	"	0.2878	"
34%	"	0.2998	"
35%	"	0.3119	"
36%	"	0.3241	"
37%	"	0.3363	"
38%	"	0.3487	"
39%	"	0.3611	"
40%	"	0.3735	"
41%	"	0.3860	"
42%	"	0.3986	"
45%	"	0.4112	"
44%	"	0.4238	"
45%	"	0.4364	"
46%	"	0.4491	"
47%	"	0.4618	"
48%	"	0.4745	"
49%	"	0.4873	"
50%	"	0.5000	"

The value for intermediate percentages may be obtained by interpolation without any serious error.

The table given only extends as far as half the diameter but can readily be extended the whole way by any reader who wishes to use it. For example as-

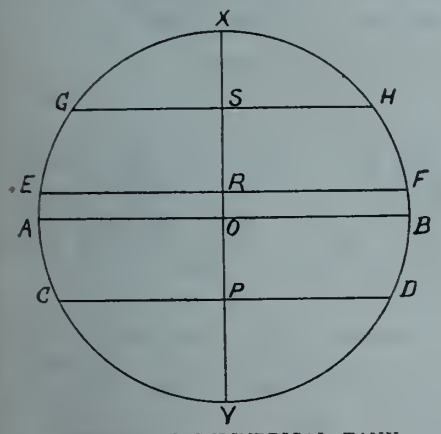

DIAGRAM OF CYLINDRICAL TANK CAPACITIES.

suming that it is being used for estimating the liquid actually in tank, and the percentage of the diameter thus counted starts from the bottom, then 51 per cent. from the bottom is 49 per cent. from the top, subtracting from unity the fraction of the capacity representing the top 49 per cent. viz., 0.4873, 51 per cent., of the diameter is found to represent 0.5127 of the capacity, 52 per cent. is 1—0.4745 or 0.5255 of the capacity, 53 per cent. 1—0.4618 or 0.5382 and so on.

Referring to the diagram which represents one of the circular ends standing vertically, if the surface of the liquid is at AB, then the tank is half full, OY being 50 per cent. of the diameter XY. If it stands at CD the tank contains 0.2523 of its capacity, PY being 30 per cent. of the diameter XY. When more than half full, proceeding as already shown, at EF the tank is 1—0.5382 full as XR is 47 per cent. of the diameters, and at GH it is 1—0.1424 or 0.8576 full, as XS is 20 per cent. of the diameter XY.

HEAT LOSS IN POWER PLANTS

By J. E. Noble.

MUCH has been written, and the half has not been told, about the heat loss in power plants. The B.t.u's wasted at present are a national economic question or ought to be, and too much can not be done towards reducing this loss.

One way of helping towards this end is to keep before engineers and owners the subject in its different phases. Bad furnace and chimney design and shafting out of line mean large losses in dry chimney gas and preventable friction. Radiation from uncovered steam pipes and defective brick work is another source of serious loss in heat units.

A Remediable Loss

One of the greatest losses, however, can be credited to poorly paid firemen who are liable to show the human side of nature by the careless "don't-care-a-curse" style of work done by this class of men; of course, there are exceptions. One of the greatest mistakes made by many otherwise competent business men is to get the cheapest labor possible for the fire-room.

Another great source of waste is heat in exhaust steam, and disregard of the stream of condensation running to the sewer. It is stated that in the average power plant the sensible heat loss in dry chimney gas will go as high as 20 per cent. of the total heat in the fuel. The use of fuel economizers, properly installed and attended to, will reduce this loss by from 25 to 50 per cent. in many plants.

Use of Economizers

The use of economizers will lower the temperature of the chimney gases and utilize the heat which formerly escaped to the atmosphere. The gas temperature in the stack should not exceed 500 degrees, less might do. Attention should be given to the brick work around the boilers, all cracks should be closed up, and soot and scale should be kept out of the boilers as much as possible. The use of a CO_2 recorder is recommended, for, while 15 to 18 pounds of air is required to burn one pound of coal, in many plants 25 pounds or more is used, being more than 50 per cent. in excess of that required. Much of this excess air is due to poor firing, air entering through holes in the fire, while some of it may enter through cracks in the boiler setting and open holes around blow-off pipes, etc.

Some of these obvious improvements have yet to be made in the plant where the writer is employed, but so far as loss due to exhaust steam or condensation is concerned, present conditions are much more satisfactory. We use the exhaust from steam engines, steam pumps, kitchen and laundry equipment, vapor baths, etc., etc. The steam from all machines using cylinder oil is first passed through oil separators, but as the separator is yet to be made that will continually remove all the oil from exhaust steam, the condensation is passed through a filtering heater after the heat of the steam is extracted for heating water and warming buildings and other work.

The drips from the separators are run to oil traps and the oil collected and filtered and used on heavy shaft bearings, as no oil once used should be used in high pressure cylinders a second time.

The Human Factor

However, to obtain efficiency in the power plant, it is necessary to spend a little cash in connection with the comfort and remuneration on the men who do the work. A great deal is written about conserving material, etc.—it is just as important to conserve the power in the workman. Shifts of 12 hours and over are common; wash basins, baths and other toilet fixtures are usually not to be found in the average plant; as a rule the fire-room is cheerless, the work dirty and the pay small, and the conditions about as bad as the health inspector will pass.

And still the owner allows such conditions to exist, and does not consider that he is selfish or unfeeling. Many large plant owners recognize the fact that the poorly paid, poorly looked after fire-room help is a mighty poor investment. Such help can, and often do, waste the amount of their wages several times over, when, if a little consideration was shown them (towards their comfort and welfare), the cost of the investment would be returned several hundred per cent., by causing an interest in the work, and a desire to do the right thing to the employer who did the right thing by them.

Seventeen men were waiting in line at a ticket window in a railway station when an excessively inebriated person thrust himself at the head of the line and shoved thirty-five cents before the ticket agent.

"Gimme ticket f' New York," he said.

"You can't go to New York on thirty-five cents," answered the agent.

The exhilarated man wavered a moment, and then was struck with a brilliant idea.

"Say," he asked, "where can I go for thirty-five cents?"

And seventeen men told him.

Question and Answer Section

Question.—Please give the ingredients and their proportion in some easily prepared freezing mixtures.—T. S.

Answer.—Using finely crushed or grated ice in place of snow, the following are simple mixtures.—Snow 1; common salt 1, reduces from + 32 to 0 deg.; snow 3; hydrochloric acid 5; from + 32 to — 27 deg.; snow 8; calcium chloride 5; from + 32 to — 40 deg. Mixtures without snow are,—ammonia chloride 5; potassium nitrate 5; sodium sulphate 8; water 16, from + 50 to + 4 deg.; ammonia nitrate 1; sodium carbonate 1; water 1, from + 50 to — 7 deg.; sodium sulphate 5; dilute sulphuric acid 4, from + 50 to + 3 deg.

* * *

Question.—(1). What is the best way to connect up three 100 horse-power locomotive type boilers to a main steam pipe or header. The outlet from each boiler is on the side of the dome, and a 4 in. pipe with two bends connects it to the main. A stop valve is located between the bends (see Fig. 1,) the dimensions being as given thereon. Considerable trouble is experienced with leaks. Would it not be better to have connection enter directly into tee-piece or header in vertical position rather than have bent pipe as shown, although the bent pipe may help some in allowing for expansion?

Would not a much smaller pipe than 10 in. be ample for the main?—F.C.

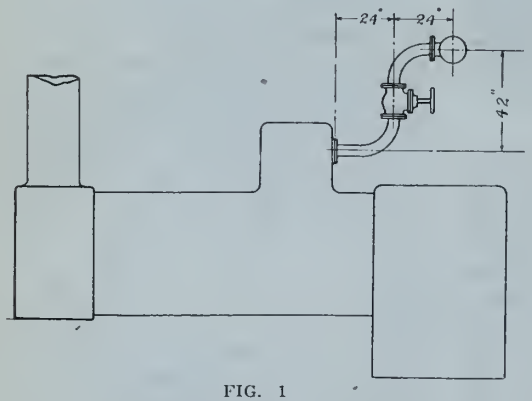

FIG. 1

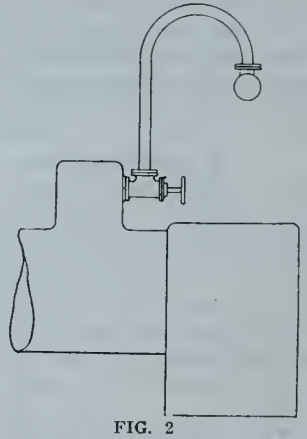

FIG. 2

STEAM HEADER CONNECTIONS TO BATTERY OF BOILERS.

Answer.—The placing of the valve in the centre of a reverse bend as formed by the 4 in. connecting pipe in Fig. 1 is decidedly bad practice. If these pipes are uncovered and a boiler is occasionally shut off, the necessity for making allowance for expansion will be very great; also if the main steam pipe is held rigidly in place there will be considerable strain set up in the connecting pipes when the plant shuts down over week ends, etc. All of this strain will come chiefly on the joints of the valve, and in lesser degree on the end joints. It is not desirable to connect up boilers to the lower side of a steam main. Should any one boiler develop priming and send a volume of water along the main, it will fill up any connecting pipes which may not be in use and cause hammering when they are cut in, while it will also give trouble when it comes to any other connecting pipe which is supplying steam.

The manner of connection shown in Fig. 2 will put the least strain on the valve body due to the longer arm of the bend, and keeps all joints away from the stressed part of the bend. If it is desired to use the existing stop valves, the angle valve shown could be replaced by a cast steel elbow or close bend, and the valve placed on top of that.

None of these arrangements overcome the objection to the steam main being higher than the boiler stop valves, and provision should be made for draining the condensation which gathers in the side of the bend when a boiler is shut off.

The existing size of main steam pipe. 10 in. is in excess of that necessary for three 4 in. pipes. The square of the diameter of the main should be equal to the sum of the square of diameter of connecting pipes. Thus $4 \times 4 = 16$. $16 \times 3 = 48$ = sum of square. $10 \times 10 = 100$ = square of main, which is twice the required size. The square root of 48 is say 7 which is the required diameter in inches of main steam pipe.

Question.—What is the proper method for determining the mechanical efficiency of an engine.—P.L.

Answer.—The mechanical efficiency of an engine is represented by the ratio of the brake-horse-power to the indicated-horse-power, or in other words the proportion of the useful work obtained to the total power imparted to the engine. Stated mathematically.

$$\text{Mechanical efficiency} = \frac{\text{B.H.P.}}{\text{I.H.P.}}$$

If, for example, indicator cards showed that an engine was developing 80 horse-power and brake tests showed 57 horse-power the mechanical efficiency would be 57-80 ths. or 71 per cent.

* * *

Question.—Please give a simple method of determining approximately the thickness of a boiler shell for any desired pressure.—M.L.

Answer.—It is presumed that the greatest safe working pressure is required. In order to determine this, three other factors must be known as follows.

Let P=Greatest safe working pressure.
D=Internal diameter of boiler in inches.
T=Thickness of plate.
f=Safe working tensile stress per sq. in. of metal.

$$P \times D = 2\,T \times f =$$

$$P = \frac{2\,T \times f}{D}$$

By substituting actual values, the result is easily calculated: thus if the plate be ½ in. thick, boiler dia. 60 in., and safe stress allowed 10,000 lbs. per sq. in.

$$P = \frac{2 \times \frac{1}{2} \times 10{,}000}{60} = 166 \text{ lbs. per sq. in. pressure.}$$

Deductions would be made from this in actual practice according to the type of joints employed, workmanship, etc. Various insurance companies have also special formulae which vary according to their individual requirements.

* * *

Question.—How many different sizes of condenser tubes are used in practice, are there any special reasons for making them as small as is usual, and could not steel be used instead of brass for the material?—H.R.

Answer.—The sizes of condenser tubes most frequently in use are five-eighths of an inch and three-quarters of an inch. These sizes are a sort of compromise and have been arrived at as the result

of many years experience of numerous builders. The function of the circulating water which passes through the tubes is to abstract the heat from the steam, and to do this efficiently all of the water which leaves the condenser should, as far as possible have attained the maximum temperature of discharge allowed. If large tubes were used, the tendency of the water would be to drag slowly along the tube surface while the cooler core of the water was forced through at a higher speed, taking less heat with it. and consequently doing less work than if smaller tubes were used and all of the water allowed to receive the heat. The question of packing the tubes also had some influence on their size, as smaller tubes give more trouble in packing! due to their increased number, while their smaller size makes them unsuited to rough handling which occasionally occurs.

Steel condensed tubes are never used because of the corrosion which takes place especially with salt water. The heat conductivity of steel tubes would also be much less than brass or special composition tubes. The galvanic action due to the brass and iron construction has a distructive effect on the tubes, but allowing for this, the superiority of brass over steel as a material for tubes is never questioned.

* * *

Question.—Why is mercury used almost exclusively in thermometers? Are there any reasons in thermometer manufacture which prevent the use of other liquids such as alcohol?—R. T.

Answer.—The principal reasons why mercury is used in preference to alcohol are that its rate of expansion is nearly uniform and the range of temperature between its freezing and boiling points being great enough to cover all ordinary requirements. The high limit of mercury thermometers is raised by filling the space above the mercury with nitrogen gas which is compressed as the mercury rises and raises the boiling points accordingly. Alcohol is used when low temperatures are to be measured owing to its resistance to freezing.

* * *

Question.—How many tons would it be safe to hang from a ¾ in. eye bolt? —N. H.

Answer.—It depends altogether on the nature of the load. If it is simply to hold a heavy object which would be a steady dead load, the permissible weight might be four times that allowed where the load was on chain blocks on some other condition where it would be subject to shock. An average strength for a common steel eye bolt would be 60,000 breaking stress. The area of a ¾ in. bolt at the root of the thread is .302 sq. in., and 60,000 × .302 = 18,120 lbs. load which it might and might not sustain, that is roughly 9 tons. If used for suspending live loads such as occur when hoisting etc., and where the load may jolt or even drop a short distance, one-tenth of the breaking load would be quite sufficient to allow so that 1,800 lbs. or less than one ton would be the permissible load.

Question.—What is meant by "Creep" in a belt. Is there any way of avoiding it?—T.K.

Answer.—Creep is the term applied to the action of belting in motion whereby it changes its position in relation to the pulleys. It is distinct from and must not be confused with "slip". It is proportional to the elasticity of the belt and varies to some extent with the load. When any one portion of a belt is on the slack side, and is approaching the driven pulley, it is under the least tension and does no work beyond sustaining its own weight. As it passes around the surface of the driven pulley, it gradually assumes the stress due to the load and stretches accordingly. It remains in the stretched condition till it reaches the driving pulley when it gradually assumes its former length as it reaches the point where it leaves. The amount of this back and forth movement on each pulley is roughly 1 per cent. of the length of the belt, so that the total loss of velocity is 2 per cent., and must be allowed for in all belting installations where accurate speeds are required. The trouble, of course, can be avoided by the use of chain belts, if circumstances render this form of transmission desirable.

* * *

Question.—What is the function of a dynamo, and of what does it consist?—C. F.

Answer.—Dynamos are mechanical appliances for converting magnetic forces into electrical energy. They are used for the generation of electrical current for lighting and power services. The principal parts of a dynamo consist of field magnets and cores, with their coils, yoke piece, armature, and commutator; brushes with their necessary fittings; the whole being mounted on a bedplate. Rotative motion of the armature is procured by belt, or direct drive from engine or other prime mover. The supply of magnetic force is maintained by the winding of numerous insulated coils of copper wire around the field magnet cores. These coils may be either part of the main lead from and to the dynamo, in which case the magnets are said to be "series" wound; or a wire may be taken from the main lead at the positive brush, wound round the magnet cores and returned to the negative brush; the magnets are then said to be "shunt" wound. Again, when the shunt and the main leads are both taken round the field magnets, the wiring is then known as "compound" wound. The various elements of the armature, as well as the armature and commutator themselves, must be insulated one from another, and from the shaft to which they are attached. The brushes are attached to a rocking frame to secure the desired contact with the commutator.

* * *

Question.—In what respect does an electric motor differ from a dynamo?—M. E.

Answer.—An electric motor when properly constructed differs in no respect from a dynamo, embodying as it does neither more nor less than a direct reversal of the method of action of the dynamo.

* * *

Question.—Describe a method for drying out an induction motor?—G. E. R.

Answer.—There are several methods for drying out an induction motor that has become damp or water soaked. Perhaps the best is to run the motor without load at reduced voltage to cause it to draw a heavy current for heating without dangerous voltage stress. The current should be from one to two times full load value, which will require from 1-6 to 1-3 full voltage for the average motor (slightly less for 25-cycle motors and perhaps slightly more for 60-cycle low-speed motors). If the rotor is of the wound type, the collector rings should be short-circuited as for normal running. This method will apply heat from the interior of the conductors of both stator and rotor.

* * *

Question.—When two single-phase watthour meters are used to measure the energy input to a two-phase induction motor, will not one meter run backward when the power-factor is less than 50 per cent?—G. E. R.

Answer.—Unlike the power-factor of a three-phase circuit, the power-factor of a two-phase circuit has no influence upon the direction in which the meters revolve. Each meter will run forward when the phase to which it is connected feeds energy to the motor. The only condition under which one meter would reverse and run backward is that the voltage of the circuit be so very badly unbalanced that all the power is taken from one phase of the line and the line voltage of the second phase be less than the counter electromotive-force of the motor, thereby causing a return of energy to the second phase of the line. However, such a badly unbalanced condition would be very unusual.

* * *

Question.—What is the ratio existing between the low-speed and high-speed starting torques of a two-speed induction motor?—G. E. R.

Answer.—Two-speed induction motors do not possess a common ratio between their low-speed and high-speed starting torques. The value of the ratio is a property of the particular design of a two-speed motor, not of two-speed motors as a class. Therefore, a specific design of two-speed motor must be considered and its characteristics must be known. The factors upon which the value of the ratio depends are: (1)—The pitch of the stator windings, i.e., whether the high-speed winding is over half-pitch and the low-speed winding is above full pitch. (2)—The end-ring resistance as compared with the bar resistance of the squirrel cage. 3—Whether the motor is designed for constant torque or torque in proportion to speed. While it is a fact that the torque per ampere at starting is ordinarily about twice as great on the low-speed, the actual delivered torque is usually somewhat greater on the high speed than on the low. However, this condition is sometimes reversed by a change in the type of winding used.

BOILER-FEED REGULATORS

PERHAPS no feature of power plant operation has been rendered more vital by reason of modern developments than that of maintaining a correct water level in steam boilers. Particularly where water tube boilers are in use,

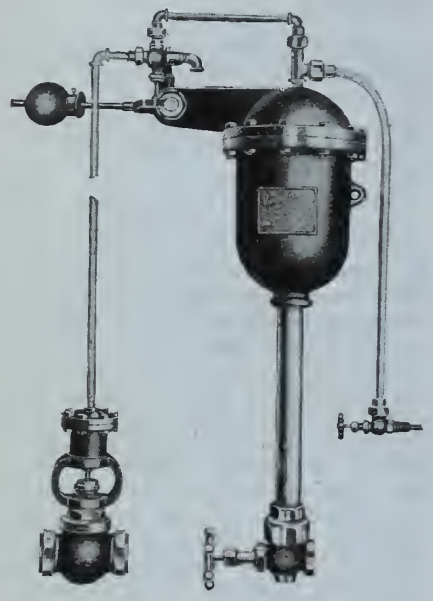

FIG. 1. "VIGILANT" FEED-WATER REGULATOR.

containing a minimum amount of water per square foot of heating surface combined with high rates of evaporation, the necessity of adopting some mechanical device to eliminate the uncertainty of human control becomes more and more evident. In common with other apparatus which has been developed with the object of eliminating the human element, the automatic boiler feed-water regulator, as instanced by the numerous types now in existence, has filled a long felt want successfully, and much of its success has been due to the fact that in addition to fulfiilling primary object of it development its adoption has been accompanied by other benefits such as economy of fuel, the generation of uniformly dry steam, increased life for the boilers, and saving of labor. As a safeguard against explosions due to neglect in hand operations, feed-water regulators are indispensable and for this feature alone if for none other, they should form a part of every boiler equipment.

Economy of Fuel

For every type of boiler there is a certain water level generally, but not always at middle gauge which allows the boiler to work with the maximum heating surface and steam space combined with the safe minimum of water. By operating the boiler constantly at this point maximum economy is obtained. However, in some cases where loads are variable and heavy, the capacity of the boiler may be temporarily increased by allowing it to fill up to the highest desirable level before the heavy load comes on, after which, by reducing the rate of feed, the boiler will steam at an increased rate as the pressure drops slightly. The question therefore arises regarding the advisability of operating at a fixed level or at a variable level, and regulators for each system are available.

Dry Steam

Any properly designed boiler when operated at a proper rating with water of average purity should not prime, but if the water level be allowed to rise too much, and an overload occur at an inopportune moment, the boiler may well earn a bad reputation which should instead be borne by the operator. It is safe to say that probably 80 or 90 per cent. of priming trouble is due to careless handling of the water level. The troubles arising therefrom are familiar to most power house operators,—wasted lubrication with consequent scoring of cylinders, water hammer with its disastrous effects when excessive, and loss of economy even when slight,—all the indirect losses due to the presence of these troubles may be avoided by insuring a safe limit to the variation of water level.

Durability

Boilers are generally allowed to run dry only once, the cost of the trouble is a new boiler, but the effect of a widely changing water level, with its variation in temperature, in decreasing the useful life of the boiler is none the less certain though somewhat slower. Few boilers possess such perfect circulation and steaming capacity that water even at 200 deg. Fahr. can be pumped in at a high rate and then allowed to steam at an increasing temperature, which will again be lowered when feeding re-com-

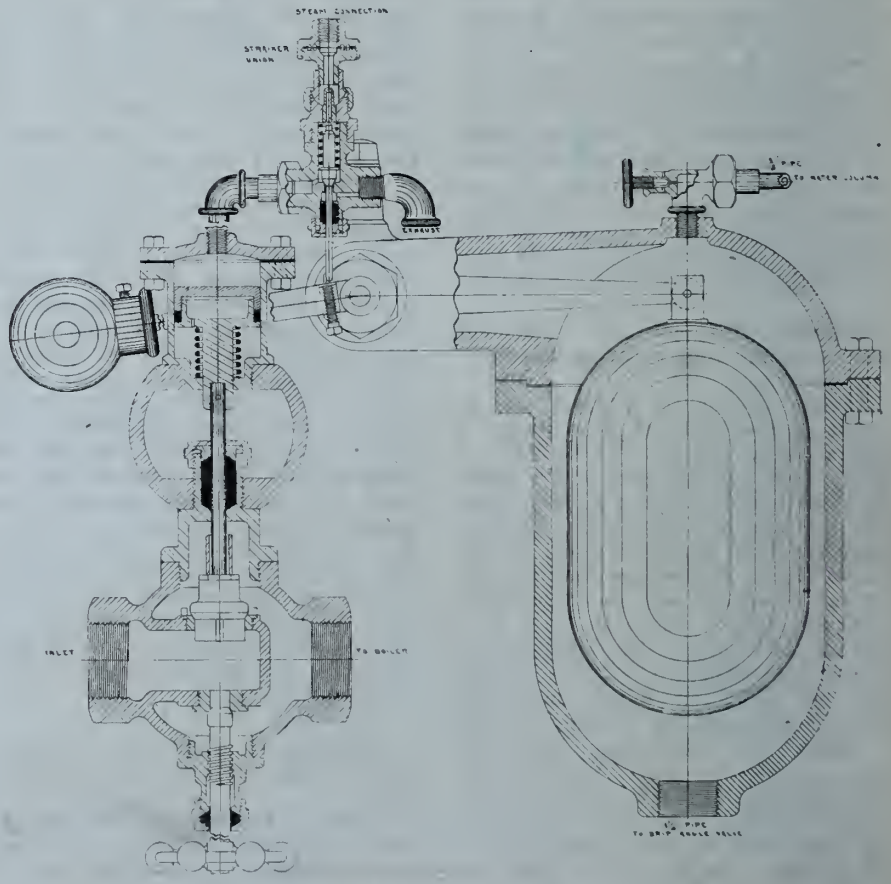

FIG. 2. SECTIONAL VIEW OF "VIGILANT" REGULATOR SHOWING ARRANGEMENT OF OPERATING MECHANISM.

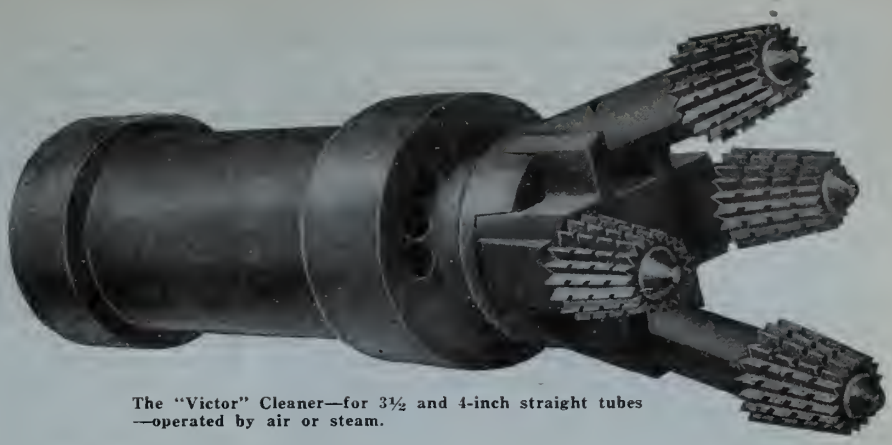


The "Victor" Cleaner—for 3½ and 4-inch straight tubes —operated by air or steam.

THE VICTOR

"The longer it runs the better it works"

This is what Mr. Christensen, Chief Engineer of the Des Moines Electric Company, said when speaking of a test made in his plant between the Liberty "Victor" Tube Cleaner and a "best" cleaner of another make. He had purchased both machines, and the test was simply to find out for his own satisfaction which machine was really the best.

He explained that at the beginning of the test it was about "nip and tuck," but when four or five boilers had been cleaned the other machine began to slow up and they were unable to get very satisfactory results. With the "Victor" Cleaner, he continued, the longer it ran the better work it accomplished.

The results of this test emphasize the claim made for the "Victor" Cleaner—that it will do as much or more work, and will last longer than any other cleaner built. These are the things that count when you have a boiler down for cleaning.

You can't afford to have a boiler idle two days for doing a cleaning job that should be done in one; neither can you afford to have the operator spend a half or more of his time making repairs to the tool.

Whether you have forty boilers with heavy scale, or only one boiler with light scale, you will find it economy in the end to use the best tool available, and for operation with air or steam that tool is the "Victor."

Catalogue "H" describes the "Victor" Cleaner. Also the "Bulldog." It's the one to send for if you are interested in getting rid of scale in the easiest and fastest way.

No scale can withstand the spurs of "Victor" Tube Cleaners.

LIBERTY MANUFACTURING COMPANY

6904 Susquehanna Street **Pittsburgh, Pennsylvania**

The "Bulldog" Cleaner—the King of all Tube Cleaners—operated by water.

mences. Such treatment may not affect a boiler adversely immediately, but the repair bill will be constant and increasing as the years roll on.

Increased efficiency on the part of the attendant is the natural outcome of the adoption of such devices. Just as surely as the safety valve, the high and low water alarm, the fusible plug and the mechanical stoker have relieved him of the strain resulting from continuous attention to numerous duties any one of which in itself may be of a minor nature but when attended to collectively involve a degree of close application which leaves little opportunity and less desire for performing his duties in a loyal and broad-minded manner.

Classification

Feed-water regulators may be divided roughly into two main types—intermittent and continuous—these again being grouped according to the manner of obtaining the motive power necessary for their operation. All regulators, no matter what type consist of two main units, the primary operating device directly affected by change of water level, and the secondary controlling valve on the feed line which is dependent on the primary for its operation. The primary is generally referred to, as the regulator, and the secondary as the controller. While the first type of feed-water regulator has been referred to as intermittent, the majority of them are not really so in the sense of stopping off the feed completely, but are arranged so that minimum flow of feed-water passes through at all times, adjustable to the requirements of any one boiler. As they do not shut off completely, the use of a high and low water alarm is desirable.

The continuous type of feed-water regulator, on the other hand is always in operation except when there is no load on the boiler resulting in maximum water level which stops the controller completely. As the boiler resumes operation, the regulator opens the controller gradually, the amount increasing as the water level decreases till at full load a maximum amount of feed-water is passing while the water level is at the height best suited for full load operation.

"Vigilant" Regulator

This apparatus is of the intermittent type and is actuated by a solid body inside of a vertical column, the weight of the body being altered as it is alternately submerged by the rise and fall of water in the column. By means of suitable mechanism, the movement of the weight is transmitted to the feed valve with resulting control of the feed-water. An exterior view of the entire apparatus is shown in Fig. 1, and a sectional drawing in Fig. 2.

Referring to Fig. 2, a small angle valve on top of the column is connected to the water gauge column at the height at which it is desired to have water level. The lower end of the column is connected to the water space of the boiler at any convenient point. The displacement weight is suspended from one end of a lever whose fulerum shaft extends out through a stuffing box and supports another lever with an adjustable counterweight. The counterweight lever has an adjusting screw set to operate a pilot valve located above, which controls the supply of steam to the operating cylinder of the controlling valve on feed pipe.

The controlling valve is similar in construction to a check valve. A stem extends from the valve to a chamber above the cast iron loop, and is connected to a piston moving in the chamber. The upper cover of the chamber forms a reservoir for water which prevents the live steam from coming in contact with the rubber cup and underneath the piston is a spring to assist in opening the valve when there is no pressure on the piston. In the lower part of the valve body is shown a by-pass or continuous feed valve which can be adjusted to suit any desired rate of boiler consumption and thus minimize the operation of the mechanism.

Assuming the device in operation, as the water in gauge column rises past the opening of the connection to regulator chamber, steam is cut off from the chamber and the contained steam then condenses, allowing the chamber to fill with water through the lower connection. The displacement weight now weighs less than it did when not submerged, and is tilted up by the counterbalance weight which allows the small pilot to seat on its lower end, and open the steam admission valve at its upper end.

The steam pressure immediately depresses the piston of controlling valve and shuts off feed. No more water can enter the boiler until the water returns to the level of the gauge connection when steam again enters the chamber and the contained water returns to its own level. The increased weight of the displacement body causes it to descend, raising the counterweight and reversing the position of the pilot valve. The steam which held the control valve is now exhausted through the lower valve seat and relieves the pressure on top of piston, thus allowing control valve to open again.

The foregoing cycle of operations are repeated as the water gets above or below the desired point, with a variation not exceeding one-half inch. The operation of the device is indicated by the counter-balance weight which is up when feeding and down when shut. This regulator is the product of Chaplin—Fulton Mfg. Co., Pittsurgh.

TRADE GOSSIP

Toronto, Ont.—The William Davies Co. will build an extension to their boiler house on Front Street East at a cost of $6.000.

Toronto, Ont.—The Etobicoke Township Council propose to build an electric light plant to supply current to the district.

Trail, B.C.—The City Council propose spending $80,000 for extensions to the waterworks plant. A by-law will be voted on.

Hespeler, Ont.—A by-law to raise $14,000, to provide for extensions to the waterworks system, has been passed by the ratepayers.

St. Mary's, Ont.—The Town Council will likely expend $1,500 for the purchase of a small motor-driven pump for the pumping plant.

Montreal, Que.—The Howard Smith Paper Mills have under consideration the installation of a 11,000-h.p. hydro-electric unit at Crabtree Mills.

Renfrew, Ont.—The town has purchased the Renfrew Power Co.'s water rights, hydraulic and electrical equipment. The price was $100,000.

Davidson, Sask.—The Town Council propose purchasing a power plant and making improvements to same. The total cost is estimated at $4,300.

Wolseley, Sask.—The Town Council have awarded a contract for a generator and exciter to the Canadian Westinghouse Co., of Hamilton.

Toronto, Ont.—The Standard Chemical Co. have awarded a contract for a 1,500 gallon per minute duplex pump to the Bawden Pump Co., Toronto.

Bala, Ont.—The Bala Electric Light & Power Co. will build a power plant. Grant & Thorpe, of Peterborough, are the general contractors.

Three Rivers, Que.—The City Council are receiving bids on four turbine pumps, each having a capacity of between 2½ and 3 million gallons per day.

Winnipeg, Man.—The Deputy Minister of Public Works has let a contract to the Canadian Westinghouse Co., for motor generator sets, at $28,360.

Niagara Falls, Ont.—The Niagara Falls Power Co. is installing a third generating unit, two having recently been completed and placed in service.

Hamilton, Ont.—The Canadian General Electric Co.'s tender of $1,420 for switchboard extensions has been accepted by the Hamilton Hydro-Electric Commission.

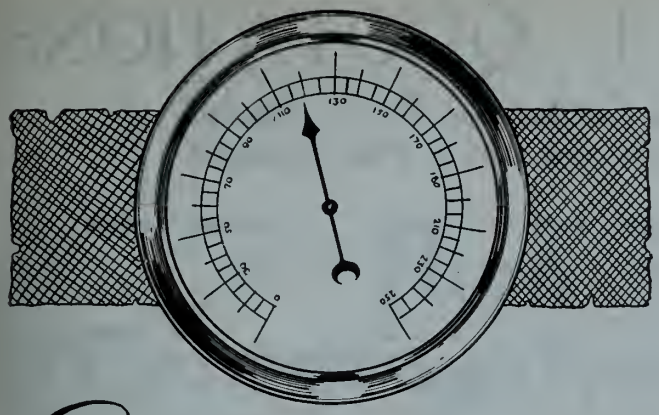
Montreal, Que.—The Montreal Tramways Co. have awarded a contract to the Canadian Westinghouse Co. for a 12,500-k.w. steam turbo-generator for the power station at Hochelaga.

Montreal, Que.—The Frick Ice & Refrigeration Co. have sold a three-ton refrigerating machine to D. D. Drulard, of Windsor, Ont., and another unit to the Montreal Arena, Montreal.

Paris, Ont.—The Town Council are calling tenders for a centrifugal pump with a capacity of 750 gallons per minute. Full particulars may be obtained from G. H. Armstrong, sec.-treasurer.

The International Engineering Works, Amherst, N.S., are building a pair of 25 ins. by 36 ins. centre crank engines for installation at the Armstrong, Whitworth Co. of Canada plant, Longueuil, Que.

Montreal, Que.—The York Manufacturing Co., York, Pa., has sold a 120-ton refrigerating machine and high side to the International Manufacturing Co., Montreal. The plant was installed by the Carrier Engineering Corp., New York.



Can you keep the pointer where it belongs?

It's getting near four o'clock. The demand for power is a trifle heavier than usual. The peak is coming. The sockets click one after another in a steady stream. The demand for steam is going up, up, up. Can You Keep The Pointer Where It Belongs?

Sturtevant
(TRADE-MARK)

Turbo-Undergrate Blower

will keep steam up. It supplies all the draft you want and just when you want it.

When you buy a blower be sure it's a Sturtevant. The Sturtevant name is a guarantee of mechanical excellence—a guarantee that you will have no breakdown and no bearing trouble. The Sturtevant Set has generous bearings with oil rings and large reservoirs. One filling will last for weeks.

To prevent the escape of steam from the casing there is a floating stuffing box. If for any reason through neglect or carelessness this is allowed to leak, there is a special "water-throw" collar which makes it impossible for steam to enter the bearings. Furthermore, the floating stuffing box makes it possible to exhaust against back pressures as high as 25 pounds.

If you have trouble getting enough steam or keeping the needle where it belongs, write us for bulletin No. 214-U.

Waterproofed with R.I.W. Toxement.

Is Your Fireproof Building Waterproof?

In specifying modern Portland Cement construction for your new building, you have minimized the chance of loss by fire. But are you protected against loss by depreciation from water?

At a small additional first cost you can make your fireproof building permanently *waterproof* with

R.I.W. (REMEMBER IT'S WATERPROOF) REG. U.S. PAT. OFF. TOXEMENT PATENTED

This integral waterproofing compound is a dry powder, mixed in small quantities with Portland Cement or clinker. It lubricates the batch of cement, concrete or stucco, and causes the ingredients to knit together in a dense, impenetrable mass.

It does not accelerate or retard the setting, and its use results in a construction that is permanently proof against salt or fresh water. Write for descriptive literature, Dept. 59.

Gates Boiler Furnace

Patented 1916

Will last three times as long as ordinary good grade Fire Brick. These blocks are inter-locking, and made so that any handy man or fireman can renew them without disturbing any of the other brick work.

DIXON'S SOLID Belt Dressing

"Is The Perfect Belt Dressing"

Put up in handy sticks and applied while the belt is in motion.

By using Dixon's Belt Dressing every ounce of "pull" in a belt is quickly made available. Yet the composition of this dressing is such that it will not cause belts to crack or harden.

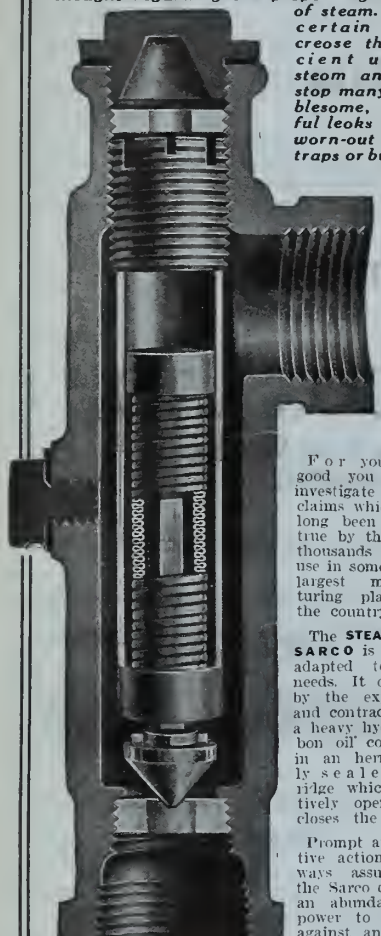
AUTOMATIC HYDRAULIC CONTROL

ON EVERY STEAM LINE

STEAM TRAP SARCO

relieves the engineer of oll worry and thought regarding the proper regulations of steam. It is certain to increose the efficient use of steom and will stop many troublesome, wosteful leoks due to worn-out valves, traps or buckets.



For your own good you should investigate our claims which have long been proven true by the many thousands now in use in some of the largest manufacturing plants in the country.

The **STEAM TRAP SARCO** is ideally adapted to your needs. It operates by the expansion and contraction of a heavy hydro-carbon oil contained in an hermetically sealed cartridge which positively opens and closes the valve.

Prompt and positive action is always assured as the Sarco develops an abundance of power to operate against any given pressure up to 2 pounds.

The **STEAM TRAP SARCO** is small, compact and supremely efficient. It may be added to your steam lines as an elbow or bend in the system. The cost is very small and steam lines may be trapped in several places at a smaller cost than with one large old style trap or bucket. By this method of using **STEAM TRAP SARCO** directly at the point of condensation, greater efficiency is secured by the elimination of long stretches of drain pipes to a central controlling trap or bucket.

The **STEAM TRAP SARCO** is the only thermostatic trap capable of positive, accurate operation in high pressure systems. Yet it is equally as practical for low pressure from one to fifty pounds.

You ought to know the Steam Trap Sarco.

30 DAYS' FREE TRIAL

Let us send you an efficient little hydraulically operated **STEAM TRAP SARCO** for 30 days' test. Take it apart. Examine it. Study the simplicity of operation. Find out by practical test what you gain by using it.
